This skin condition is characterized by thickened, gray-brown velvety plaques seen in areas of flexure such as the back of the neck, the axillae, the crease beneath the breast, the waist, and the groin (Fig. 17-7) (Panidis, 1995). Thought to be a cutaneous marker of insulin resistance, acanthosis nigricans may be found in individuals with or without PCOS. Insulin resistance leads to hyperinsulinemia, which is believed to stimulate keratinocyte and dermal fibroblast growth, producing the characteristic skin changes (Cruz, 1992). Acanthosis nigricans is more often found in obese women with PCOS (50 percent incidence) than those with PCOS and normal weight (5 to 10 percent). Less commonly, it is seen with genetic syndromes or malignancy of the gastrointestinal tract, such as adenocarcinoma of the stomach or pancreas (Torley, 2002).

Photograph shows acanthosis nigricans on the back of the neck.

Impaired Glucose Tolerance and Type 2 Diabetes Mellitus

Women with PCOS are at increased risk for impaired glucose tolerance (IGT) and type 2 DM. Based on oral glucose tolerance testing of obese women with PCOS, the prevalence of IGT and DM is approximately 30 percent and 7 percent, respectively (Legro, 1999). Similar findings were reported in a group of obese adolescents with PCOS (Palmert, 2002). In addition, β cell dysfunction that is independent of obesity has been reported in patients with PCOS (Dunaif, 1996a).

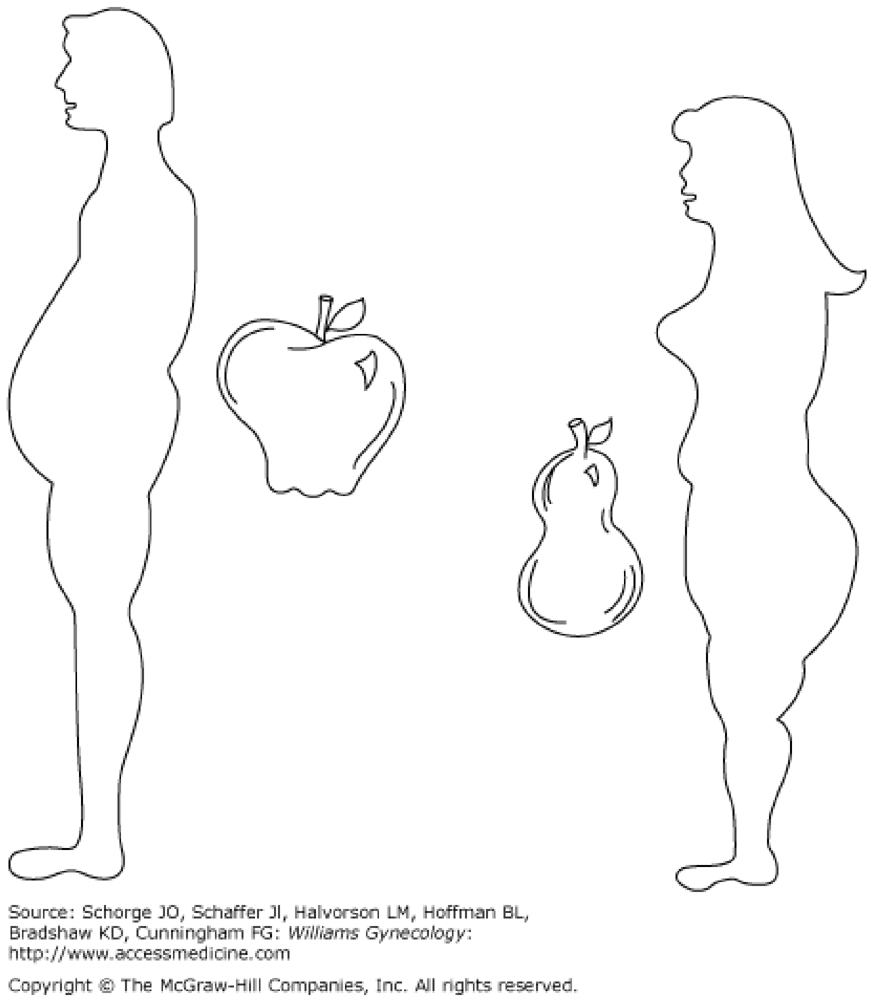
DYSLIPIDEMIA

The classic atherogenic lipoprotein profile seen in PCOS is characterized by elevated low-density lipoproteins (LDL), triglyceride levels, and total cholesterol:high-density lipoprotein (HDL) ratios, and by depressed HDL levels (Banaszewska, 2006). These changes may increase the risk of cardiovascular disease in women with PCOS independent of total cholesterol levels. Following criteria of the National Cholesterol Education Program, the prevalence of dyslipidemia in PCOS approaches 70 percent (Legro, 2001; Talbott, 1998).

OBESITY

Compared with age-matched controls, women with PCOS are more likely to be obese, as reflected by an elevated body mass index (BMI) and waist:hip ratio (Talbott, 1995). This ratio reflects an android or central pattern of obesity, which itself is an independent risk factor for cardiovascular disease (Fig. 17-8) (Nishizawa, 2002).

FIGURE 17-8



Obesity may present with a central distribution of body fat, also described in lay terms as an "apple-shaped" pattern. Alternatively, fat may predominate in the hips and buttocks in what is often termed a "pear-shaped" distribution.

As noted earlier, insulin resistance is believed to play a large role in the pathogenesis of PCOS and is often exacerbated by obesity (Dunaif, 1989). Thus, obesity can have a synergistic effect on PCOS and can worsen ovulatory dysfunction, hyperandrogenism, and the appearance of acanthosis nigricans.

Obstructive Sleep Apnea

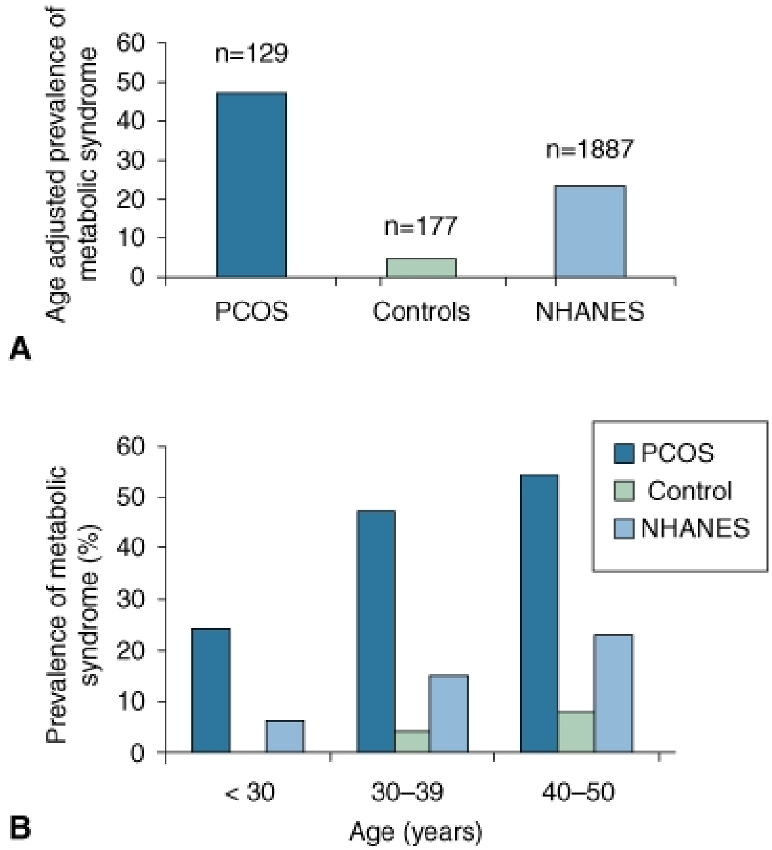
Obstructive sleep apnea is more common in women with PCOS and is likely related to central obesity and insulin resistance (Fogel, 2001; Vgontzas, 2001). However, some research has determined that the risk of sleep apnea is 30- to 40-fold higher in women with PCOS compared with weight-matched controls. This evidence points towards a link between obstructive sleep apnea and the metabolic and hormonal abnormalities associated with PCOS.

Metabolic Syndrome and Cardiovascular Disease

This syndrome is characterized by insulin resistance, obesity, atherogenic dyslipidemia, and hypertension. The metabolic syndrome is associated with an increased risk of cardiovascular disease (CVD) and type 2 DM (see Chap. 1, Metabolic Syndrome) (Schneider, 2006). The prevalence of metabolic syndrome is reported to be approximately 45 percent in women with PCOS compared with 4 percent in age-adjusted controls (Fig. 17-9) (Dokras, 2005). Polycystic ovarian syndrome shares several endocrine features with the metabolic syndrome, although definitive evidence for an increased incidence of CVD in women with PCOS is lacking (Legro,

1999; Talbott, 1998; Rebuffe-Scrive, 1989). However, in a small group of women with PCOS, Dahlgren and colleagues (1992) predicted a relative risk of myocardial infarction of 7.4. Another 10-year surveillance study showed an odds ratio of 5.91 for CVD in overweight Caucasian women with PCOS (Talbott, 1995). Thus, evidence suggests that women with PCOS should have CVD factors identified and treated (see Table 1-14) (Mosca, 2004).

FIGURE 17-9



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

A. Women with polycystic ovarian syndrome (PCOS) have an increased risk of metabolic syndrome compared with age-adjusted controls and with women from NHANES III. B. In women with PCOS, the risk of metabolic syndrome begins earlier than in controls or those from NHANES III. The Third National Health and Nutrition Survey (NHANES III) collected data from a representative sample of the noninstitutionalized civilian U.S. population from 1988 through 1994 (Ford, 2002). *(From Dokras, 2005, with permission.)*

In addition to components of the metabolic syndrome, other markers of subclinical disease link PCOS and CVD. Women with PCOS have been found to have a greater incidence of left ventricular diastolic dysfunction and increased internal and external carotid artery stiffness (Lakhani, 2000; Tiras, 1999). Moreover, in affected women, several studies have found greater endothelial dysfunction, which is described as an early event in the evolution of atherosclerosis (Diamanti-Kandarakis, 1999; Orio, 2004; Paradisi, 2003; Tarkun, 2004).

Endometrial Neoplasia

In women with PCOS, a threefold increased risk of endometrial cancer has been reported. Endometrial hyperplasia and endometrial cancer are long-term risks of chronic anovulation, and neoplastic changes in the endometrium are felt to arise from chronic unopposed estrogen (see Chap. 33) (Coulam, 1983). Moreover, the effects of hyperandrogenism and hyperinsulinemia to lower SHBG levels and increase circulating estrogen levels may add to this risk.

Few women who develop endometrial cancer are younger than 40 years, and most of these premenopausal women are obese or have chronic anovulation or both (Peterson, 1968; Rose, 1996). Thus, the American College of Obstetricians and Gynecologists (2000) recommends endometrial assessment in any woman older than 35 years with abnormal bleeding, and in those younger than 35 years who are suspected of having anovulatory uterine bleeding refractory to medical management (see Chap 8, Medical Treatment).

Infertility

Infertility or subfertility is a frequent complaint in women with PCOS and results from anovulatory cycles. Moreover, in women with infertility secondary to anovulation, PCOS is the most common cause and accounts for 80 to 90 percent of cases (Adams, 1986; Hull, 1987). Infertility evaluation and treatment in women with PCOS is described in more detail in Chapter 20, Ovulation Induction.

Pregnancy Loss

Women with PCOS who become pregnant are known to experience an increased rate (30 to 50 percent) of early miscarriage compared with a baseline rate of approximately 15 percent in the general population (Balen, 1993; Homburg, 1998b; Regan, 1990; Sagle, 1988; Schieve, 2003; Watson, 1993). The etiology of early miscarriage in women with PCOS is unclear. Initially, retrospective and observational studies showed an association between LH hypersecretion and miscarriage (Homburg, 1998a; Howles, 1987). However, one prospective study showed that lowering LH levels with GnRH agonists failed to show a benefit to this therapy (Clifford, 1997).

Others have suggested that insulin resistance is related to miscarriage in these women. To lower loss rates, an insulin level lowering drug, metformin (Glucophage, Bristol-Myers Squibb, New York, NY), has been investigated. Metformin, a biguanide, lowers serum insulin levels by reducing hepatic glucose production and increasing the sensitivity of liver, muscle, fat, and other tissues to the uptake and effects of insulin.

Several retrospective studies have indicated that women with PCOS taking metformin during pregnancy have a lower incidence of miscarriage (Glueck, 2001; Jakubowicz, 2002). In addition, a prospective study demonstrated a lower miscarriage rate for women conceiving while taking metformin compared with those using clomiphene citrate (Palomba, 2005). Similarly, another randomized trial demonstrated a reduced rate of pregnancy complications in women with PCOS using metformin during pregnancy compared with those given placebo (Vanky, 2004). However, until further randomized controlled trials are performed studying the effects of metformin (a category B drug) on pregnancy outcome, the use of this medication in gestation for miscarriage prevention is not recommended.

Complications in Pregnancy

Several pregnancy and neonatal complications have been associated with PCOS. One large meta-analysis found women with PCOS to have a two- to threefold higher risk of gestational diabetes, pregnancy-induced hypertension, preterm birth, and perinatal mortality, unrelated to multifetal gestations (Boomsma, 2006). In addition, many women with PCOS require the use of ovulation induction medications or in vitro fertilization, which substantially increases the risk of multifetal gestations and resultant increase in maternal and neonatal complications (see Chap. 20, Multifetal Gestation) (Fauser, 2005).

DIAGNOSIS

Polycystic ovarian syndrome is often referred to as a diagnosis of exclusion (Fig. 17-10). Thus, routine exclusion of other potentially serious disorders that may clinically appear like PCOS is warranted (Table 17-4).

Table 17-4 Differential Diagnoses of Ovulatory Dysfunction and Hyperandrogenism

	Laboratory Testing	Indicative Results[a]
Causes of oligo- or anovulation		
PCOS	Testosterone level	Usually increased
	DHEAS level	May be mildly increased
	LH:FSH ratio	Typically greater than 2:1
Hyperthyroidism	TSH level	Decreased
Hypothyroidism		Increased
Hyperprolactinemia	PRL level	Increased
Hypogonadotropic hypogonadism	FSH, LH, E_2 levels	All decreased
POF	FSH, LH levels	Increased
	E_2 levels	Decreased
Causes of hyperandrogenism		
PCOS		
Late-onset CAH	17-OH-P level	>200 ng/dL
Androgen-secreting ovarian tumor	Total T level	>200 ng/dL
Androgen-secreting adrenal tumor	DHEAS level	>700 μg/dL
Cushing syndrome	Cortisol level	Increased
Exogenous androgen use	Toxicology screen	Increased

[a] Based on reference laboratory ranges of normal

CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; E_2 = estradiol; FSH = follicle-stimulating hormone; LH = luteinizing hormone; 17-OH-P = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; POF = premature ovarian failure; PRL = prolactin; T = testosterone; TSH = thyroid-stimulating hormone.

FIGURE 17-10

Algorithm for diagnosis of polycystic ovarian syndrome. ACTH = adrenocorticotropin hormone; CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; PCOS = polycystic ovarian syndrome; 17-OHP = 17-hydroxyprogesterone. *(From Hunter, 2003, with permission.)*

Thyroid-Stimulating Hormone and Prolactin

Thyroid disease may frequently lead to menstrual dysfunction similar to that seen in women with PCOS (Chap. 8, Thyroid Disease). Accordingly, a serum TSH level is typically measured during evaluation. Similarly, hyperprolactinemia is a well-known cause of menstrual irregularities and occasionally amenorrhea. Elevated prolactin levels lead to anovulation through inhibition of GnRH

pulsatile secretion from the hypothalamus (see Chap. 15, Hyperprolactinemia).

Testosterone

Tumors of the ovary or adrenal are a rare but serious cause of androgen excess. A variety of ovarian neoplasms, both benign and malignant, may produce testosterone and lead to virilization. *Specifically, women with an abrupt onset, typically within several months, or sudden worsening of virilizing signs should prompt concern for a hormone-producing ovarian or adrenal tumor.* Symptoms may include deepening of the voice, frontal balding, severe acne or hirsutism or both, increased muscle mass, and clitoromegaly (Table 17-5). Accordingly, serum testosterone levels may be used to exclude these tumors (see Chap. 36).

Table 17-5 Clinical Features of Virilization
Hirsutism
Acne
Androgenic alopecia
Clitoromegaly
Deepening of the voice
Increased muscle mass
Decreased breast size
Amenorrhea

Free testosterone levels are more sensitive than total testosterone levels as an indicator of hyperandrogenism. Although improving, current free testosterone assays lack a uniform laboratory standard (Miller, 2004). For this reason, total testosterone levels remain the best approach for excluding a tumor. Threshold values beyond 200 ng/dL of total testosterone warrant evaluation for an ovarian lesion (Derksen, 1994).

Pelvic sonography is the preferred method to exclude an ovarian neoplasm in a female with very high androgen levels. Alternatively, computed tomography (CT) or magnetic resonance (MR) imaging may also be used in this setting.

Dehydroepiandrosterone Sulfate

Dehydroepiandrosterone sulfate is produced essentially exclusively by the adrenal gland. Therefore, serum DHEAS levels above 700 μg/dL are highly suggestive for the presence of an adrenal neoplasm. Adrenal imaging with abdominal CT or MR imaging is indicated for any patient with DHEAS levels that exceed this value.

Gonadotropins

During evaluation of amenorrhea, FSH and LH levels are typically measured to exclude premature ovarian failure and hypogonadotropic hypogonadism (see Table 17-4). Past this, however, LH and FSH levels have little additive value to the diagnosis of PCOS. Although classically LH levels measure at least twofold higher than FSH levels, this is not found in all women with PCOS. Specifically, one third of women with PCOS have circulating LH levels in the normal range, a finding more common in obese patients (Arroyo, 1997; Taylor, 1997). Moreover, serum LH levels are affected by sample timing within a menstrual cycle, use of oral contraceptive pills, and body mass index.

17-Hydroxyprogesterone

The term congenital adrenal hyperplasia (CAH) describes several autosomal recessive disorders that result from complete or partial deficiency of an enzyme involved in cortisol and aldosterone synthesis, usually 21-hydroxylase or less frequently 11-hydroxylase (see Fig. 15-13). Symptoms of CAH and their severity are varied. It may present in the neonate with ambiguous genitalia and life-threatening hypotension. Alternatively, symptoms may be milder and delayed until adolescence or adulthood. In this late-onset form of CAH, symptoms reflect accumulation of precursor C_{19} steroid hormones. These precursors are converted to

dehydroepiandrosterone, androstenedione, and testosterone, and signs of virilization predominate.

Specifically, deficiency of the most commonly affected enzyme, 21-hydroxylase, leads to accumulation of its substrate, 17-hydroxyprogesterone. Serum values are drawn in the morning from a fasting patient. Threshold values of 17-hydroxyprogesterone that measure more than 200 ng/dL should prompt an adrenocorticotropin hormone (ACTH) stimulation test. With this test, synthetic ACTH, 250 μg, is injected intravenously, and a serum 17-hydroxyprogesterone level is measured 1 hour later. Levels above 1000 ng/dL are indicative of late-onset CAH.

Cortisol

Cushing syndrome results from prolonged exposure to elevated levels of either endogenous or exogenous glucocorticoids. Of these, the syndrome is most frequently caused by administration of exogenous glucocorticoids. Alternatively, the term Cushing disease is reserved for cases of Cushing syndrome in which the constellation of symptoms stem from increased secretion of adrenocorticotropin hormone (ACTH) by a pituitary tumor. Individuals with Cushing syndrome may present with many symptoms suggestive of PCOS such as menstrual dysfunction, acne or hirsutism, truncal obesity, dyslipidemia, and glucose intolerance. Classically, moon facies and abdominal purple striae are also noted.

Initial laboratory testing is directed at confirming excessive glucocorticoid production. Analysis of a 24-hour urine collection for urinary free cortisol excretion is the preferred initial test. Normal values are less than 90 μg per 24 hours, and those in excess of 300 μg per day are considered diagnostic for Cushing syndrome (Kirk, 2000; Meier, 1997). Alternatively, a dexamethasone suppression test may be selected to avoid the difficulty of obtaining a 24-hour urine collection in some women. This, however, has a higher false-positive rate. One milligram of dexamethasone is taken orally at 11 pm, and a plasma cortisol level is measured at 8 am the following morning. Normal values are below 5 μg/dL (Crapo, 1979).

Measurements of Insulin Resistance and Dyslipidemia

Many women with PCOS have insulin resistance and compensatory hyperinsulinemia. Although the consensus meeting in Rotterdam suggested that tests of insulin resistance are *not* required to diagnose or treat PCOS, these tests are often used to evaluate glucose metabolism and impaired insulin secretion in these women (The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004).

The gold standard for evaluating insulin resistance has been the hyperinsulinemic euglycemic clamp. Unfortunately, this test as well as the intravenous glucose tolerance test (IV GTT) requires an intravenous line and frequent sampling, are labor and time intensive, and are not practical in a clinical setting. Accordingly, other less sensitive surrogate markers that evaluate insulin resistance are used and include: (1) 2-hour glucose tolerance test (2-hr GTT), (2) fasting serum insulin level, (3) homeostasis model assessment of insulin resistance (HOMA IR), (4) quantitative insulin sensitivity check (QUICKI), and (5) calculation of serum glucose:insulin ratios.

Of these, a 2-hr GTT is frequently used to exclude impaired glucose tolerance (IGT) and type 2 DM, and is particularly important in obese PCOS patients who are at higher risk for both (Table 17-6). Over time, women with PCOS demonstrate a worsening of IGT, with a reported conversion rate of about 2 percent per year to type 2 DM. Measurements of fasting glucose and glycohemoglobin levels will not detect the early worsening of insulin resistance and glucose intolerance. This affirms the importance of periodic assessment of glucose tolerance with a 2-hr GTT in this population (Legro, 1999, 2005).

Table 17-6 Diagnosis of Impaired Glucose Tolerance and Diabetes Mellitus			
	Normal Range	**Impaired Glucose Tolerance**	**Diabetes Mellitus**
Fasting blood glucose level	≤100 mg/dL	100â€"125 mg/dL	≥126 mg/dL
2-hr GTT	≤140 mg/dL	140â€"199 mg/dL	≥200 mg/dL

2-hr GTT = 2-hour oral glucose tolerance test.

From Alberti, 1998, with permission.

In addition to assessment of insulin resistance, a fasting lipid profile is used to evaluate any signs of dyslipidemia.

Endometrial Biopsy

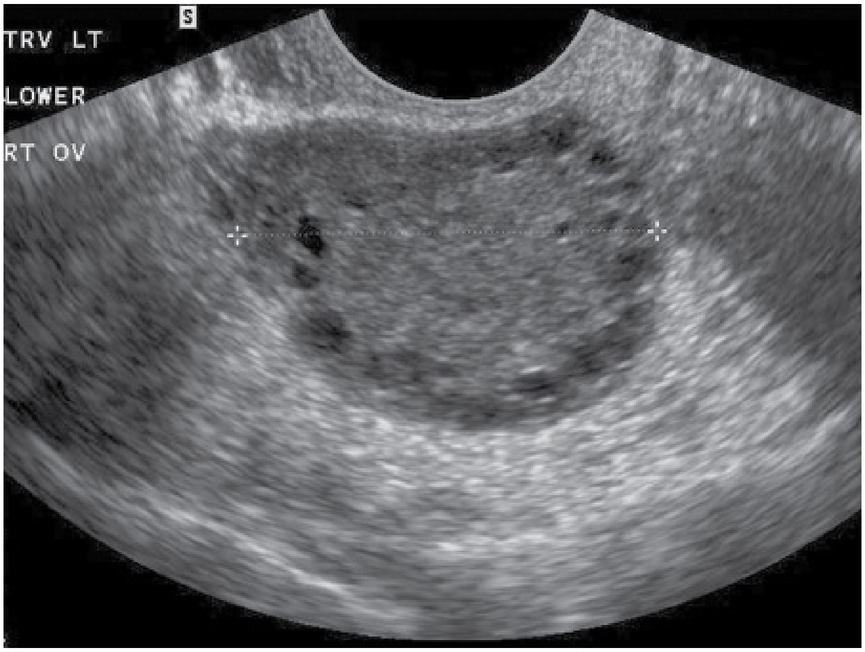
An endometrial biopsy is recommended in women older than age 35 with abnormal bleeding and in younger women with anovulatory bleeding refractory to hormonal treatment. Steps of this procedure are found in Chapter 8, Endometrial Biopsy.

Sonography

Histologically a polycystic ovary (PCO) displays increases in volume, number of ripening and atretic follicles, cortical stromal thickness, and number of hilar cell nests (Hughesdon, 1982). Many of these tissue changes can be seen sonographically, and a pelvic sonographic examination is commonly used to evaluate the ovaries in women with suspected PCOS. Sonography is particularly important for women with PCOS seeking fertility and in women with signs of virilization. A high-definition transvaginal approach is superior and has a higher detection rate of PCO than the transabdominal route. However, a transabdominal route is preferred for virginal adolescents.

Sonographic criteria for polycystic ovaries from the 2003 Rotterdam conference include ≥12 small cysts (2 to 9 mm in diameter) or an increased ovarian volume (>10 mL) or both (Fig. 17-11). Often there is an increased amount of stroma relative to the number of follicles (Balen, 2003). Only one ovary with these findings is sufficient to define PCOS. However, criteria do not apply to women taking combination oral contraceptive pills (The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004).

FIGURE 17-11



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Transvaginal sonography displays multiple small hypoechoic cysts. *(Courtesy of Dr. Elysia Moschos.)*

In contrast, other findings are not valuable diagnostically. For example, the typical "black pearl necklace" appearance in which follicles are distributed just underneath the capsule in a row, and the perceived increase in stromal echogenicity have been eliminated as diagnostic criteria. Moreover, a polycystic ovary should not be confused with a multicystic ovary, which is normal size, contains six or more follicles without peripheral displacement, and lacks an increase in central stromal volume.

Remarkably, studies using sonography have shown that at least 23 percent of young women have ovaries that exhibit PCO morphology, yet many of these women have no other symptoms of PCOS (Clayton, 1992; Polson, 1988). In addition, a polycystic appearance of the ovaries can often be found in other conditions of androgen excess, such as congenital adrenal hyperplasia, Cushing syndrome, and exogenous use of androgenic medications. For this reason, PCO morphology found during sonographic examination is not used solely to make the diagnosis of PCOS.

TREATMENT

The choice of treatment for each symptom of PCOS depends on a woman's goals and the severity of endocrine dysfunction. Thus, anovulatory women desiring pregnancy will undergo a significantly different treatment than adolescents with menstrual irregularity and acne.

Observation

Women with PCOS who have fairly regular cycle intervals (8 to 12 menses per year) and mild hyperandrogenism may choose not to be treated. In these women, however, periodic screening for dyslipidemia and diabetes mellitus is warranted.

Weight Loss

For obese women with PCOS, lifestyle changes focused on diet and exercise are paramount to treatment at each stage of life. Even a modest amount of weight loss (5 percent of body weight) can result in restoration of normal ovulatory cycles in some women. This improvement results from reductions in insulin and androgen levels, the latter mediated through increases in SHBG levels (Huber-Buchholz, 1999; Kiddy, 1992; Pasquali, 1989).

The optimal diet that best improves insulin sensitivity is not known. Diets high in carbohydrates increase insulin secretion rates, whereas diets high in protein and fat lower those rates (Bass, 1993; Nuttall, 1985). However, very-high-protein diets are concerning with respect to stresses on kidney function. Moreover, they afford only short-term weight loss initially with lesser benefits over time (Legro, 1999; Skov, 1999). Thus, it appears that a well-balanced hypocaloric diet offers the most benefit in treating obese women with PCOS.

Exercise

Exercise is known to have a beneficial effect in treating patients with type 2 DM (Nestler, 1998). The most dramatic effect of lifestyle intervention was published in 2002 as the Diabetes Prevention Program. Women and men at risk for diabetes were asked to lose at least 7 percent of their weight and to exercise for 150 minutes each week. This group had a twofold greater benefit in delaying the onset of diabetes compared with a group given metformin alone. Both groups fared better than a placebo group (Knowler, 2002). Few studies, however, have looked specifically at the effect of exercise on insulin action in women with PCOS (Jaatinen, 1993).

Oligo-Ovulation and Anovulation

Women with oligo-ovulation or anovulation typically have fewer than eight menses per year, often skip menses for several months at a time, or simply have amenorrhea. Flow may be scanty or very long and heavy, resulting in anemia.

COMBINATION ORAL CONTRACEPTIVE PILLS

A first-line treatment for menstrual irregularities is combination oral contraceptive pills (COCs), which will induce regular menstrual cycles. In addition, COCs reduce androgen levels. Specifically, COCs suppress gonadotropin release, which results in decreased ovarian androgen production. Moreover, the estrogen component increases SHBG levels. The progestin component antagonizes the endometrial proliferative effect of estrogen, thus reducing risks of endometrial hyperplasia due to unopposed estrogen.

Theoretically, progestin-containing pills that contain norethindrone; a third-generation progestin, such as norgestimate or desogestrel; or the newer progestin, drospirenone, are preferred to COCs containing progestins with more androgenic properties. However, no pill has shown superiority compared with another in reducing hirsutism (Sobbrio, 1990). Alternative combination hormonal options include the contraceptive patch and vaginal ring (see Chap. 5, Transdermal Administration).

In initiating therapy, if a woman's last menses was more than 4 weeks prior, a pregnancy test is indicated. If negative, progesterone is given to produce a withdrawal bleed prior to COC initiation. Typical regimens include: medroxyprogesterone acetate (MPA) (Provera, Pfizer, New York, NY), 10 mg orally daily for 10 days; MPA, 10 mg orally twice daily for 5 days; or micronized progesterone (Prometrium, Solvay Pharmaceuticals, Marietta, GA), 200 mg orally daily for 10 days.

CYCLIC PROGESTINS

In patients who are not candidates for combination hormonal contraception, progesterone withdrawal is recommended every 1 to 3 months. Examples of regimens used include: MPA, 5 to 10 mg orally daily day for 12 days, or micronized progesterone, 200 mg orally each evening for 12 days. Patients should be counseled that intermittent progestins will not reduce symptoms of acne or hirsutism nor provide contraception.

INSULIN-SENSITIZING AGENTS

Although the use of insulin sensitizers in PCOS has not been approved by the Food and Drug Administration (FDA), they have been found to be increasingly beneficial for both metabolic and gynecologic issues. For example, metformin may be used to treat women with infertility and PCOS. This drug improves peripheral insulin sensitivity by reducing hepatic glucose production and increasing target tissue sensitivity to insulin. Metformin decreases androgens in both lean and obese women, leading to increased rates of spontaneous ovulation (Batukan, 2001; Essah, 2006; Haas, 2003; Kocak, 2002; Lord, 2003).

A number of studies have demonstrated that up to 40 percent of anovulatory women with PCOS will ovulate, and many will achieve pregnancy with metformin alone. (Diamanti-Kandarakis, 1998; Fleming, 2002; Neveu, 2007; Velazquez, 1997). Metformin is a category B drug and is safe to use as an ovulatory induction agent. As such, it may be used alone or in concert with other medications such as clomiphene citrate (see Chap. 20, Ovulation Induction). Specifically, metformin has been shown to increase

the ovulatory response to clomiphene citrate in patients who were previously clomiphene-resistant (Nestler, 1998). Despite these positive findings regarding metformin and ovulation induction, Legro and colleagues (2007) in a randomized prospective study of 626 women found higher live-birth rates with clomiphene citrate alone (22 percent) than with metformin alone (7 percent).

A rare adverse side effect of metformin is lactic acidosis and is almost exclusively found in patients with renal insufficiency, liver disease, or congestive heart failure. More common side effects are gastrointestinal, and these can be minimized by starting at a low dose and gradually increasing the dose over several weeks to an optimal level. In clinical studies, 1500 to 2000 mg in divided doses daily with meals are typically used.

The thiazolidinediones are another class of medications also used for patients with diabetes mellitus and include rosiglitazone (Avandia, GlaxoSmithKline, Philadelphia, PA) and pioglitazone (Actos, Takeda Pharmaceuticals, Deerfield, IL). These agents bind to insulin receptors on cells throughout the body, causing them to become more responsive to insulin and thereby lowering serum glucose and insulin levels. Similar to metformin, rosiglitazone and pioglitazone have been shown to improve ovulation in some patients (Azziz, 2001; Dunaif, 1996b; Ehrmann, 1997). However, the glitazones are category C drugs and thus should be used as ovulation induction agents in rare cases and discontinued once pregnancy is achieved.

Hirsutism

In the treatment of hirsutism, a primary goal is lowering androgen levels to halt further conversion of vellus hairs to terminal ones. However, medical therapies will not eliminate abnormal hair growth already present. Moreover, treatments may require 6 to 12 months before clinical improvement is apparent. For this reason, clinicians should be familiar with temporary hair removal methods that may be used in the interim. Permanent cosmetic therapies may then be implemented once medications have reached maximal therapeutic effect.

COMBINATION ORAL CONTRACEPTIVES

As described earlier, COCs are effective in establishing regular menses and lowering ovarian androgen production. As an additional effect, the estrogen component of these pills leads to increased SHBG levels. With higher SHBG levels, a greater amount of free testosterone is bound and thus becomes biologically unavailable at the hair follicle.

GONADOTROPIN-RELEASING HORMONE AGONISTS

As described in Chapter 9, GnRH Agonists, gonadotropin-releasing hormone (GnRH) agonists effectively lower gonadotropin levels over time, and in turn subsequently lower androgen levels. Despite their effectiveness in treating hirsutism, administration of these agents is not a preferred long-term treatment method due to associated bone loss, high cost, and menopausal side effects.

EFLORNITHINE HYDROCHLORIDE

This antimetabolite topical cream is applied twice daily to areas of facial hirsutism and is an irreversible inhibitor of ornithine decarboxylase. This enzyme is necessary for hair follicle cell division and function, and its inhibition results in slower hair growth. It does not permanently remove hair, and thus women are required to continue routine methods of hair removal while using this medicine.

Clinical results from eflornithine hydrochloride (Vaniqa, SkinMedica, Carlsbad, CA) may require 4 to 8 weeks of use. However, clinical trials have shown that approximately one third of patients have marked improvement after 24 weeks of eflornithine use compared with placebo, and 58 percent showed some overall improvement in hirsutism scores (Balfour, 2001).

ANDROGEN-RECEPTOR ANTAGONISTS

Antiandrogens are competitive inhibitors of androgen binding to the androgen receptor (Farquhar, 2003; Moghetti, 2000; Venturoli, 1999). Although these agents are effective in the treatment of hirsutism, they carry a risk for several side effects. Metrorrhagia may frequently develop. In addition, as antiandrogens, these drugs bear a theoretical risk of pseudohermaphroditism in male fetuses of women using such medications in early pregnancy. Accordingly, these drugs are commonly used in conjunction with oral contraceptive pills, which prompt regular menses and provide effective contraception.

None of the antiandrogen agents are approved by the FDA for treatment of hyperandrogenism and thus are used off-label.

Spironolactone (Aldactone, Pfizer, New York, NY), in a dosage of 50 to 100 mg orally twice daily is the primary antiandrogen used currently in the United States. In addition to its antiandrogen effects, this drug also affects hair conversion through its direct inhibition of 5α-reductase. Spironolactone is also a potassium-sparing diuretic. As such, it should not be prescribed for chronic use in combination with agents that can also raise blood potassium levels, such as potassium supplements, angiotensin-converting enzyme (ACE) inhibitors, nonsteroidal anti-inflammatory drugs such as indomethacin, or other potassium-sparing diuretics.

In Europe, Canada, and Mexico, the preferred antiandrogen is cyproterone acetate, usually marketed in an oral contraceptive pill. However, this agent is not approved by the FDA (Van der Spuy, 2003). Flutamide is another nonsteroidal antiandrogen marketed for the treatment of prostate cancer, but is rarely used for hirsutism due its potential hepatotoxicity.

5α-REDUCTASE INHIBITORS

Conversion of testosterone to DHT may be effectively decreased by the 5α-reductase inhibitor finasteride. This drug is available as a 5-mg tablet for prostate cancer (Proscar, Merck, Whitehouse Station, NJ) and a 1-mg tablet for the treatment of male alopecia (Propecia, Merck). Most studies have used 5-mg daily doses and have found finasteride to be modestly effective in the treatment of hirsutism (Fruzzetti, 1994; Moghetti, 1994).

Side effects are low with finasteride, although decreased libido has been noted. However, as with other antiandrogens, the risk of male fetal teratogenicity is present, and effective contraception must be used concurrently.

HAIR REMOVAL

Hirsutism is often treated by mechanical means, and these include both depilation and epilation techniques. In addition to hair removal, lightening hair color with bleach is an additional cosmetic option.

Depilation

Depilation describes hair removal above the skin surface. Shaving is the most common form and does not exacerbate hirsutism, contrary to the myth that it will increase hair follicle density. Alternatively, topical chemical depilatories are also effective. Available in gel, cream, lotion, aerosol, and roll-on forms, these agents contain calcium thioglycolate, which breaks disulfide bonds between hair protein chains causing hair to breakdown and separate easily from the skin surface.

EPILATION

Mechanical Removal

In contrast to depilation, epilation removes the entire hair shaft and root, and includes techniques such as plucking, waxing, threading, electrolysis, and laser treatment. Threading, also known as "khite" in Arabic, is a fast method for removing entire hairs and is commonly used in the Middle East and India. Hairs are snared within a outstretchedstrand of a twisted cotton thread and pulled out.

Thermal Destruction

Although waxing and plucking allow effective temporary hair removal, permanent epilation may be achieved with thermal destruction of the hair follicle. Electrolysis, performed by a trained individual, involves placement of a fine electrode and passage of electric current to destroy individual follicles. It requires repetitive treatments over several weeks to months, can be painful, and may result in scarring.

Alternatively, laser therapy uses specific laser wavelengths to permanently destroy follicles. During this process, termed *selective photothermolysis,* only target tissues absorb laser light and are heated. Surrounding tissues fail to absorb the selective wavelength and receive minimal thermal damage. For this reason, light-skinned women with dark hairs are better candidates for laser treatment due to the selective wavelength absorption by their hair.

Advantageously, laser treatment can cover a wider surface area than electrolysis and therefore requires fewer treatments. It causes less pain, but is expensive and can result in dyspigmentation.

Prior to any epilation technique, topical anesthetics may be prescribed. Specifically, a topical cream combination of 2.5-percent lidocaine and 2.5-percent prilocaine (EMLA cream, AstraZeneca, Wilmington, DE) can be applied as a thick layer that remains for 5

to 10 minutes and is removed just prior to epilation. Recommended adult dosing is 2.5 g per 2 x 2-inch area of skin treated.

Acne

One part of acne treatment is similar to that for hirsutism and involves lowering of androgen levels. Therapy may include: (1) combination oral contraceptive pills; (2) antiandrogens such as spironolactone or flutamide, which inhibit binding of androgen to its receptor; or (3) 5¤-reductase inhibitors such as finasteride.

In addition to lowering androgen levels, other therapies may be added. For this reason, women with moderate to severe acne may benefit from consultation with a dermatologist (Table 17-7).

Table 17-7 Algorithm of Acne Treatment

	Mild		**Moderate**		
Therapy	**Comedonal**	**Papular/Pustular**	**Papular/Pustular**	**Nodular**	**Severe, Nodular**
First-line therapy	T. retinoid	T. retinoid + BPO or BPO/AB	T. retinoid + oral antibiotic + BPO or BPO/AB	T. retinoid + oral antibiotic Â± BPO or BPO/AB	Oral isotretinoin
Alternatives	Salicylic acid			Oral isotretinoin	Oral antibiotic + T. retinoid + BPO or BPO/AB
Alternatives for female patients			Hormonal therapy + T. retinoid Â± BPO or BPO/AB	Hormonal therapy + T. retinoid Â± BPO or BPO/AB	Hormonal therapy + oral antibiotic + T. retinoid Â± BPO or BPO/AB
Maintenance therapy	T. retinoid Â± BPO or BPO/AB		T. retinoid Â± BPO or BPO/AB		T. retinoid Â± BPO or BPO/AB

AB = topical antibiotic; BPO = benzoyl peroxide; BPO/AB = benzoyl peroxide and topical antibiotic combination agent; T. retinoid = topical retinoid.

From Zaenglein, 2006, with permission.

TOPICAL AND SYSTEMIC ANTIBIOTICS

Topical antibiotics typically include erythromycin and clindamycin, whereas oral antibiotics most often used for acne include doxycycline, minocycline, and erythromycin. Oral antibiotics are more effective than topical therapies, but can have a variety of side effects such as sun sensitivity and gastrointestinal upset.

TOPICAL BENZOYL PEROXIDE

Benzoyl peroxide is an excellent antimicrobial and anti-inflammatory agent. It is the active ingredient in many over-the-counter products used for acne. Some prescription products also combine 5-percent benzoyl peroxide with antibiotics such as clindamycin or erythromycin.

TOPICAL RETINOIDS

Derived from vitamin A, topical retinoids regulate the follicular keratinocyte and normalize its desquamation. In addition, this group of agents also has direct anti-inflammatory properties, and thereby targets two factors linked to acne vulgaris (Table 17-8) (Zaenglein, 2006). The most commonly used agent with retinoid activity is tretinoin (Retin-A Micro, Ortho Dermatological, Skillman, NJ; Avita, Mylan Pharmaceuticals, Morgantown, WV), although adapalene (Differin, Galderma Laboratories, Fort Worth, TX) and tazarotene (Tazorac, Allergen, Irvine CA) have also been shown to be effective (Gold, 2006; Leyden, 2006). Initially, a pea-sized dab sufficient to cover the entire face is applied every third night and progressively increased as tolerated to nightly

application (Krowchuk, 2005). Tretinoin may cause a transient worsening of acne during the first weeks of treatment.

Table 17-8 Topical Retinoids

Retinoid	Formulation	Strength (%)
Tretinoin	Cream	0.025, 0.05, 0.1
	Gel	0.01, 0.025
	Liquid	0.05
	Microsphere gel (Retin-A Micro)	0.04, 0.1
	Polymerized cream (Avita)	0.025
	Polymerized gel (Avita)	0.025
Adapalene (Differin)	Cream	0.1
	Gel	0.1
	Solution	0.1
Tazarotene (Tazorac)	Cream	0.05, 0.1[a]
	Gel	0.05, 0.1[a]

[a] Indicated for psoriasis.

From Zaenglein, 2006, with permission.

Concerning teratogenicity, tretinoin and adapalene are category C drugs and thus are not recommended for use during pregnancy or breast feeding. However, epidemiologic studies currently do not support a link between topical retinoids and birth defects (Jick, 1993; Loureiro, 2005). Tazarotene is category X and similarly should not be used during these times.

ISOTRETINOIN

Oral isotretinoin (Accutane, Roche Pharmaceuticals, Nutley, NJ) is an analog of vitamin A that is highly effective for the treatment of severe recalcitrant acne. Despite its efficacy, oral isotretinoin is teratogenic if taken during the first trimester of pregnancy. Malformations typically involve the cranium, face, heart, central nervous system, and thymus. Therefore isotretinoin administration should be limited to women using a reliable form of contraception.

Acanthosis Nigricans

Optimal treatment for acanthosis nigricans should be directed towards decreasing insulin resistance and hyperinsulinemia (Field, 1961). Specifically, a few studies have shown an improvement in acanthosis nigricans with insulin sensitizers (Walling, 2003). Other methods, including topical antibiotics, topical and systemic retinoids, keratolytics, and topical corticosteroids have been tried with limited success (Schwartz, 1994).

Surgical Therapy

Although ovarian wedge resection is now rarely performed, laparoscopic ovarian drilling has been shown to restore ovulation in a significant number of women with PCOS that were found to be resistant to clomiphene citrate (see Section 41-32, Ovarian Drilling) (Hendriks, 2007).

Rarely, oophorectomy is a viable option for women not seeking fertility who exhibit signs and symptoms of ovarian hyperthecosis

and accompanying severe hyperandrogenism. Ovarian and adrenal androgen-secreting neoplasms should be treated surgically (see Chap. 36).

ANATOMIC DISORDERS: INTRODUCTION

Anatomic disorders of the female reproductive system occur frequently and may result from genetic mutation, developmental arrest, or environmental insults that may exert their effects at critical stages of embryonic development. Disorders range from congenital absence of the vagina and uterus, to defects in lateral or vertical fusion of the mÃ¼llerian ducts, to the formation of external genitalia that are ambiguous in sexual differentiation. A variety of anatomic defects may also be found in the urinary excretory system. Because of the intertwined development of these two systems, organs from both are commonly involved in urogenital tract disorders.

NORMAL EMBRYOLOGY

Overview

A basic comprehension of the rather complex embryology of the reproductive system aids in clarifying the nature of various malformations and in understanding their association with other genitourinary anomalies (Shatzkes, 1991). The urogenital system is functionally divided into the urinary system and the genital system. The urinary organs include the kidney, the ureters, the bladder, and the urethra. The reproductive organs consist of the gonads, the ductal system, and the external genitalia. Like most organ systems, urogenital tract development involves a complex interplay of multiple cell types, and it occurs during a relatively narrow time window. The temporal pattern of gene expression and the spatial relationships of the developing tissues is vitally important for normal development (Park, 2005).

Both the urinary and genital systems develop from the intermediate mesoderm, which extends along the entire length of the embryo (Moore, 1988). During initial folding of the embryo in the horizontal plane, a longitudinal ridge of this intermediate mesoderm develops along each side of the primitive abdominal aorta and is called the urogenital ridge. The urogenital ridge then differentiates into the nephrogenic and genital ridges. The genital ridges develop into the primordial gonads and are discussed in the next section. The nephrogenic ridges instead give rise to the paired mesonephric ducts, also termed wolffian ducts. These ducts connect the mesonephric kidneys to the cloaca, which is a common opening into which the embryonic urinary, genital, and alimentary tracts join (Fig. 18-1A).

Embryonic development of the female genitourinary tract. *(From Schatzkes, 1991, with permission.)*

Recall that evolution of the renal system passes sequentially through the pronephric and mesonephric stages to reach the permanent metanephric system. The ureteric bud arises from the mesonephric duct at approximately the fifth week of fetal life. It lengthens to become the metanephric duct (ureter) and induces differentiation of the metanephros, which will eventually become the final functional kidney after degeneration of the mesonephric kidney at 10 weeks (Fig. 18-1B).

The paired paramesonephric, also known as mÃ¼llerian ducts, develop from an invagination of the coelomic epithelium at about the sixth week, and grow on either side between the developing gonad and mesonephric duct. The caudal portions of the mÃ¼llerian ducts approximate one another in the midline and end behind the cloaca near the mesonephric ducts (Fig. 18-1C). The cloaca is divided by formation of the urorectal septum by the seventh week and is separated to create the rectum and the urogenital sinus (Fig. 18-1D). The urogenital sinus is considered in three parts (1) the cephalad or vesicle portion, which will form the urinary bladder (2) the middle or pelvic portion, which creates the female urethra; and (3) the caudal or phallic part, which will give rise to the distal vagina and the greater vestibular (Bartholin), urethral, and paraurethral (Skene) glands. During differentiation of the urinary bladder, the caudal portion of the mesonephric ducts is incorporated into the trigone portion of the bladder wall. Consequently, the caudal portion of the metanephric ducts (ureters) penetrates the bladder with distinct and separate orifices (Fig. 18-1D).

The close association between the mesonephric (wolffian) and paramesonephric (mÃ¼llerian) ducts has important clinical relevance because developmental insult to either system is often associated with anomalies that involve the kidney, ureter, and the reproductive tract. For example, Kenney and colleagues (1984) showed that up to 50 percent of females with uterovaginal malformations have associated urinary tract anomalies.

Gonadal Differentiation

Although the gonads and reproductive tract complete their final maturation during puberty, critical developmental steps occur during the embryonic and fetal periods. Histologically, the genital ridge begins as coelomic epithelium with underlying mesenchyme. The major cellular components of the genital ridge include the primordial germ cells and somatic cells. In both 46,XX and 46,XY embryos, the primordial germ cells are first identified as large polyhedral cells in the yolk sac. These cells migrate by ameboid motion to the dorsal mesentery and then onto the undifferentiated genital ridge.

The embryonic reproductive tract is capable of developing along either male or female lines. From this point onward, the presence or absence of gonadal determinant genes determines fetal gender development (Taylor, 2000). Sexual differentiation is dependent upon the genetic sex that is determined at fertilization of the X-bearing oocyte by either an X- or Y-chromosome-bearing sperm. In the presence of the sex-determining region of the Y (SRY) locus on the Y chromosome, the gonads develop as testes. Other important gonadal development factors include SF-1, SOX 9, WT1, WNT4, and DAX-1 (Viger, 2005). Other key factors have been described and are known to act at the transcriptional level (Park, 2005).

In males, cells in the medullary region of the primitive sex cord differentiate into Sertoli cells, and these cells organize to form the testicular cords (Fig. 18-2). Testicular cords are identifiable at 6 weeks and consist of these Sertoli cells and tightly packed germ cells. Early in the second trimester, the cords develop a lumen and become seminiferous tubules. Development of a testis-specific vasculature is crucial for normal testicular development (Ross, 2005).

Development of the paramesonephric and mesonephric ducts in the male and female embryo. *(From Larsen, 2001, with permission.)*

The developing Sertoli cells begin to secrete mÃ¼llerian-inhibiting substance (MIS) during weeks 7 to 8 of development. This gonadal hormone causes regression of the ipsilateral paramesonephric (mÃ¼llerian duct) system and this involution is completed by 9 to 10 weeks' gestation (Marshall, 1978). MÃ¼llerian-inhibiting substance may also control the rapid gubernacular growth necessary for the transabdominal descent of the testis. Serum MIS levels remain elevated in boys during childhood and then decline at puberty to the low levels seen in adult men. In contrast, girls have undetectable levels of MIS until the onset of puberty when serum MIS levels become measurable. The clinical significance of MIS, however, in pubertal and adult women is unknown.

In the testes, Leydig cells arise from the original mesenchyme of the gonadal ridge and lie between the testicular cords. Their differentiation begins approximately 1 week after Sertoli cell development. The Leydig cells begin to secrete testosterone by 8 weeks' gestation, and testosterone production peaks at weeks 15 to 18 as a result of stimulation of the testes by human chorionic gonadotropin (hCG). Testosterone acts in a paracrine manner on the ipsilateral mesonephric (wolffian) duct to promote virilization of the duct into the epididymis, vas deferens, and seminal vesicle. The androgens testosterone and dihydrotestosterone (the 5α reduced metabolite of testosterone, formed peripherally in the genital skin) are essential for the development of the male phenotype. These androgens control the differentiation and growth of the internal and external genitalia and also prime male differentiation of the brain.

In the female embryo, without the influence of the SRY gene, the bipotential gonad develops into an ovary. This development follows that of the testes by about 2 weeks and is characterized by the absence of testicular cords in the gonad. Ovarian determinant genes, although likely playing an active role in gonadal morphogenesis, are required only at later stages of development (Taylor, 2000). The primitive sex cords degenerate and the mesothelium of the genital ridge forms secondary sex cords (see Fig. 18-2). These secondary sex cords become the granulosa cells and the follicular structures that surround the germ cells. The medullary portion of the gonad regresses and forms the rete ovarii within the ovarian hilum. The primordial germ cells proliferate by mitosis and reach a peak number of 5 to 7 million by 20 weeks' gestation. At this time, the fetal ovary demonstrates mature organization with the presence of stroma and primordial follicles containing oocytes. The oocytes begin meiosis and arrest at the diplotene phase of meiosis I until the oocyte undergoes ovulation after menarche. Atresia of the oocytes starts in utero, leading to a reduced number of germ cells at birth (Fig. 14-1). A scheme of prenatal reproductive system development is presented in Fig. 18-3.

Development of the reproductive system. *(From Wilson, 1981, with permission.)*

Ductal System Development

Sexual differentiation of the reproductive ducts begins early in the fetal period and is attributed to the influence of gonadal hormones (testosterone and MIS) on the mesonephric (wolffian) and paramesonephric (mÃ¼llerian) ducts.

In the female, in the absence of MIS, the mÃ¼llerian ducts persist. These ducts grow caudally and along with the mesonephric ducts become enclosed in peritoneal folds that later give rise to the broad ligaments of the uterus. At about 10 weeks' gestation, the two distal portions of the mÃ¼llerian ducts approach each other in the midline and begin to fuse even before they reach the urogenital sinus. The fused ducts form a tube with a single lumen called the uterovaginal canal, which then inserts into the urogenital sinus at MÃ¼ller tubercle (Fig. 18-1E). This canal forms the uterus and upper portion of the vagina (Fig. 18-1F).

In a normal female, the uterine corpus and cervix differentiate, and the uterine wall thickens by 12 weeks' gestation. Initially, the upper pole of the uterus contains a thick midline septum that undergoes dissolution to create the uterine cavity. Dissolution of the uterine septum is usually completed by 20 weeks. The unfused cephalad portions of the mÃ¼llerian ducts become the fallopian tubes (Fig. 18-1F). Any failure of lateral fusion of the two mÃ¼llerian ducts or failure to reabsorb the septum between them results in separate uterine horns or some degree of persistent midline uterine septum. Moreover, vaginal agenesis is caused by failed

caudal migration of these ducts.

The distal third of the vagina develops from the bilateral sinovaginal bulbs, which arise from the urogenital sinus (Fig. 18-4A). The most inferior portion of the uterovaginal canal becomes occluded by a cellular mass derived from the sinovaginal bulbs, termed the vaginal plate (Fig. 18-4B). The cells of the vaginal plate desquamate during the second trimester, allowing for full canalization of the vaginal lumen (Fig. 18-4C). Defects in vertical fusion caused by incomplete canalization of this plate can lead to a persistent transverse vaginal septum. Septa can develop at varying levels within the vagina and be of various thicknesses (Fig. 18-5).

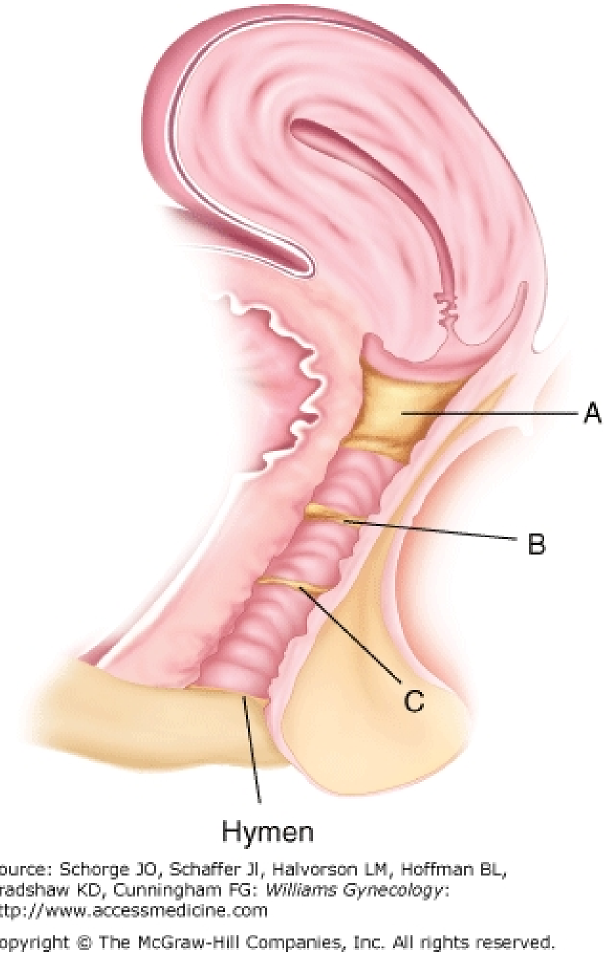
FIGURE 18-5



Potential locations of a transverse vaginal septum are noted by **A, B** , and **C.** An imperforate hymen is also shown. *(From Rock, 1982, with permission.)*

The hymen is the partition that remains to a varying degree between the dilated, canalized, fused sinovaginal bulbs and the urogenital sinus. The hymen usually becomes perforated shortly before or after birth. An imperforate hymen represents persistence of this membrane (Fig. 18-4C).

Although in each sex the ducts marked for degeneration do regress, vestigial remnants can be found and may become clinically apparent. In females, mesonephric remnants may give rise to structures such as Gartner duct cysts and to tubular epoÃ¶phoron and paroÃ¶phoron found in the mesoovarium (see Fig. 18-2). In males, a small vestige of the paramesonephros called the appendix testis may be identified.

External Genitalia

Early development of the external genitalia is similar in both sexes. By 6 weeks' gestation, three external protuberances have developed surrounding the cloacal membrane. These are the left and right genital swellings, which meet ventrally to form the third protuberance, the genital tubercle (Fig. 18-6A). Ultimately, the genital swellings become the labioscrotal folds. The urogenital sinus extends onto the surface of the enlarging genital tubercle to form the urethral groove, which is flanked on either side by the urethral folds and lies within the labioscrotal folds. By week 7 of gestation, the urogenital membrane ruptures exposing the cavity of the urogenital sinus to the amniotic fluid (Fig. 18-7). The genital tubercle elongates to form the phallus in males and the clitoris in females. The coronary sulci that surround the phallus represent the primordium of the glans penis and glans clitoris.

Development of the lower urinary and gastrointestinal tracts. (*From Sadler, 2000, with permission.*)

It is not until week 12 of gestation that one is able to visually identify a difference between male and female external genitalia (Fig. 18-8). In the male fetus, because of the effects of dihydrotestosterone (DHT) formed locally by the 5-α reduction of testosterone, the anogenital distance lengthens, the phallus enlarges, the labioscrotal folds fuse to form the scrotum, and subsequently the urethral folds merge to enclose the penile urethra (Fig. 18-6B). In the female fetus, in the absence of DHT, the anogenital distance does not lengthen, and the labioscrotal and urethral folds do not fuse (Fig. 18-6C). The genital tubercle bends caudally to become the clitoris and the urogenital sinus becomes the vestibule of the vagina. The labioscrotal folds become the labia majora, whereas the urethral folds persist as the labia minora (Gell, 2003).

CONGENITAL AMBIGUITY OF THE GENITAL TRACT

Assignment of sex to the newborn at the time of birth usually involves a simple assessment of the external genitalia and a straightforward declaration of male or female gender. Ambiguous external genitalia in a newborn may pose a true medical emergency and present an important diagnostic challenge (Fig. 18-9). Genital ambiguity results from abnormal or inappropriate androgen exposure in utero. Table 18-1 presents a classification scheme for the evaluation of the newborn with sexual ambiguity.

Table 18-1 Classification of Ambiguous Genitalia

Category I	Female pseudohermaphroditism
Category II	Male pseudohermaphroditism
Category III	Disorders of genetic or gonadal development
	A. Gonadal dygenesis
	B. True hermaphroditism
	C. Embryonic testicular regression

Female Pseudohermaphroditism (Category I)

PATHOPHYSIOLOGY

Discordance between gonadal sex (46,XX) and phenotypic appearance of the external genitalia (masculinized) results from excessive androgen exposure of an embryo or fetus. The ovaries and female internal ductal structures such as the uterus, cervix, and upper vagina are present. Accordingly, all patients with female pseudohermaphroditism are potentially fertile. The external genitalia, however, are virilized to a varying degree. This depends on the amount and the timing in embryonic development of androgen exposure. As a result, virilization may display an entire spectrum from modest clitoromegaly to development of a phallus with a penile urethra.

Excessive androgen exposure may stem from adrenal abnormalities or nonadrenal sources. Fetal congenital adrenal hyperplasia due to deficiency of 21-hydroxylase enzyme (CYP21) is the most common cause of female pseudohermaphroditism, with an incidence of approximately 1:14,000 live births (White, 2000). In addition, 11-β-hydroxylase (CYP11B) and 3β-hydroxysteroid dehydrogenase deficiency can also lead to ambiguous genitalia (see Fig. 15-13). Nonadrenal causes include maternal exposure to drugs such as testosterone, danazol, norethindrone, and other androgen derivatives. Maternal virilizing ovarian tumors, such as luteoma of pregnancy and Sertoli-Leydig cell tumor or virilizing adrenal tumors may be other sources. Fortunately, these neoplasms infrequently cause fetal virilization because of the tremendous ability of placental syncytiotrophoblasts to convert C_{19} steroids to estradiol (Cunningham, 2005).

TREATMENT

The three embryonic structures that are commonly affected by high androgen levels are the clitoris, labioscrotal folds, and urogenital sinus. Accordingly, a successful surgical correction must deal with all of these structural abnormalities to ensure a good cosmetic result and adequate sexual function. The objectives of feminizing genitoplasty are to: decrease the size of the enlarged clitoris while maintaining vascularity and sensory innervations; reduce and feminize the labioscrotal folds; and most importantly, address the urogenital sinus, which usually involves creating a separate vaginal introitus in the perineum (Hensle, 2002). Adequacy of the vagina for sexual intercourse is a major factor in these individuals if they desire fertility.

Male Pseudohermaphroditism (Category II)

PATHOPHYSIOLOGY

Insufficient androgen exposure of a fetus destined to be a male leads to male pseudohermaphroditism. The karyotype is 46,XY and testes are present. The uterus is generally absent as a result of normal embryonic MIS production. These patients are most often sterile from abnormal spermatogenesis and have a smaller or inadequate phallus for sexual function.

The etiology of male pseudohermaphroditism may involve: testicular enzyme defects in the biosynthesis of testosterone, peripheral enzyme defects, or abnormalities in the androgen receptor. Within the testes, there are five enzyme defects associated with impaired testosterone production. These include deficiencies of: (1) cholesterol side-chain cleavage enzyme (P450SCC); (2) 3β-hydroxysteroid dehydrogenase; (3) 17-α-hydroxylase; (4) 17, 20 desmolase (P450c17a); and (5) 17β-hydroxysteroid dehydrogenase. The latter two enzyme deficiencies can also cause congenital adrenal hyperplasia.

Peripherally, a defect in the enzyme 5α reductase leads to impaired conversion of testosterone to DHT, the active androgen in the peripheral tissue.

Finally, the androgen receptor may be defective and result in androgen-insensitivity syndrome (AIS). The gene for the androgen receptor is found on the long arm of the X chromosome. Mutations may result in the production of a nonfunctional receptor that will not bind androgen. Alternatively, mutations may lead to receptors that bind androgen but are unable to effect full transcriptional activation. The estimated incidence of AIS ranges from 1 in 13,000 to 41,000 live births (Bangsboll, 1992; Blackless, 2000).

PRESENTATION AND TREATMENT

As a result, there may be complete resistance, with no genital ambiguity (external genitalia appear as normal female), or an incomplete form associated with varying degrees of genital ambiguity. Milder forms of AIS have been described in men with infertility and poor virilization. Patients with complete androgen receptor insufficiency (CAIS), however, appear as phenotypically normal girls at birth and often present at puberty with primary amenorrhea. These girls develop breasts during pubertal maturation, but are found to have a blind-ending vagina and scant pubic and axillary hair. Laboratory evaluation demonstrates elevated LH levels, normal or slightly elevated male testosterone levels, and a 46,XY karyotype.

Treatment consists of replacement with physiologic levels of estrogen and creation of a functional vagina either by dilation or surgical vaginoplasty (Treatment). Additionally, surgical excision of the testes after puberty is recommended to decrease the associated risk of germ cell tumors in these individuals (see Chap. 36, Dysgerminoma). In adult life, those with CAIS have a female gender identity with a total inability to respond to androgens. Several reports suggest that these women have normal sexual function, but these reports were based on small sample sizes without using validated measures of sexual function (Lewis, 1986; Vague, 1983; Wisniewski, 2000). In contrast, Minto and colleagues (2003) evaluated 66 adult women with CAIS and found that 90 percent had some sexual difficulties compared with the general female population. Most commonly encountered problems included sexual infrequency and vaginal penetration difficulty.

Disorders of Genetic or Gonadal Development (Category III)

Several conditions, such as gonadal dysgenesis, true hermaphroditism, and embryonic testicular regression, may all lead to the development of ambiguous or infantile genitalia.

GONADAL DYSGENESIS

Gonadal dysgenesis results most often from nondisjunction of parental chromosomes and leads to abnormal gonadal development

and streak gonads. In 50 to 60 percent of patients with gonadal dysgenesis the karyotype is 45,X, and this condition is commonly called Turner syndrome. The classic stigmata of Turner syndrome include short stature (final height less than 58 inches), widely spaced nipples, and webbed neck. Additional physical findings are listed in Table 16-6. In these patients, associated problems may include cardiac anomalies (especially coarctation of the aorta), renal anomalies, hearing impairment, otitis media, and mastoiditis. They also carry an increased risk of hypertension, achlorhydria, diabetes mellitus, and Hashimoto thyroiditis. This syndrome may be recognized in childhood, but some patients are not diagnosed until adolescence, when they present with short stature, primary amenorrhea, hypergonadotropic hypogonadism, and prepubertal female genitalia. The uterus and vagina are normal and capable of responding to exogenous hormones.

Other patients with gonadal dysgenesis have a mosaic karyotype (e.g., 46,XX/45,X) or a structural abnormality of the second X chromosome. They may exhibit some or all of the stigmata of classic Turner syndrome. Patients with mosaicism are more likely to have some pubertal maturation. Gonadal failure is indicated by elevated gonadotropin levels.

Alternatively, the term *pure gonadal dysgenesis* includes patients with normal stature and gonadal abnormality of Turner syndrome. The karyotype may be 46,XX or 46,XY. The lack of a testis in XY patients results from the lack of testicular determining factors on the Y chromosome. As a result, streak gonads do not produce androgens or mÃ¼llerian inhibiting substance. This condition is also known as *Swyer syndrome* . The patients appear as normal prepubertal females including a normal mÃ¼llerian system. Because of a Y chromosome is present, these patients are at increased risk of gonadal tumors and thus require removal of the gonads.

TRUE HERMAPHRODITISM

A true hermaphrodite has both ovarian and testicular gonadal tissue. The most common karyotype associated with true hermaphroditism is 46,XX, followed by 46,XX/46,XY. The phenotype of a 46,XX true hermaphrodite includes a unilateral ovotestis with a contralateral ovary or testis, or bilateral ovotestes. The gonadal location varies from abdominal to inguinal to scrotal. The nature of the internal ductal system depends on the ipsilateral gonad and its degree of differentiation. The testicular products, MIS and testosterone, determine to what degree the internal ductal systems are masculinized or feminized. External genitalia are usually ambiguous and usually are undermasculinized due to an inadequate amount of testosterone.

In 46,XX sex-reversed males, male sexual differentiation occurs in the presence of a 46,XX karyotype. In this condition, varying lengths of DNA from the Y chromosome are translocated to the X chromosome during meiosis. The SRY gene is abnormally translocated to the X chromosome in about 60 percent of 46,XX sex-reversed males (Kolon, 1998; Schweikert, 1982). In individuals without translocated SRY, it is likely that downstream Y, X, or autosomal testicular determining factor genes are present or activated.

The presence of SRY guides the gonad to develop along testicular lines, and testicular hormone function is near normal. The mÃ¼llerian system regresses due to the production of MIS. Androgen production allows development of the wolffian system and masculinization of the external genitalia. Spermatogenesis, however, is absent due to absence of certain genes on the long arm of the Y chromosome. These individuals are not usually diagnosed until puberty or during an evaluation for infertility. The testes are usually small and may be cryptorchid. The penis may be small, and hypospadias is present in about 10 percent. Semen analysis reveals azoospermia due to absent spermatogenesis.

EMBRYONIC TESTICULAR REGRESSION

Lastly, embryonic testicular regression or agonadism may occur in a 46,XY individual. In these settings, MIS may or may not be produced, and therefore the uterus may be present or absent. Similarly, the karyotype may or may not be abnormal, that is, 46,XY/45X (mixed gonadal dysgenesis); 46,XX (true hermaphroditism); or 46,XY (embryonic testicular regression). There is variable androgen secretion among these disorders and thus phenotypic presentations may be diverse.

DEFECTS OF THE BLADDER AND PERINEUM

Description and Patient Presentation

Bladder exstrophy is thought to be caused by failure of the cloacal membrane to be reinforced by an ingrowth of mesoderm. The bilaminar cloacal membrane lies at the caudal end of the germinal disc and forms the infraumbilical abdominal wall. The normal ingrowth of mesoderm between the ectodermal and endodermal layers of the cloacal membrane leads to formation of the lower abdominal musculature and the pelvic bones. The cloacal membrane may prematurely rupture. Depending on the extent of the infraumbilical defect and the stage of development at which it ruptures, bladder exstrophy, cloacal exstrophy, or epispadias results (Gearhart, 1992).

The incidence of bladder exstrophy has been estimated to be between 1 in 10,000 and 1 in 50,000 (Lattimer, 1966; Rickham, 1960). This anomaly displays a predilection for males and the male:female gender ratio derived from multiple series approximates 2:1. Additional evidence for a genetic mode of transmission was noted by Shapiro and co-workers (1985). They determined that the risk of bladder exstrophy in the offspring of individuals with bladder exstrophy and epispadias is 1 in 70 live births, a 500-fold greater incidence than in the general population.

All cases of exstrophy have the characteristic widening of the symphysis pubis caused by the outward rotation of the innominate bones. This rotation accounts for the increased distance between the hips in these individuals and their associated waddling gait. In addition, Stanton (1974) noted that 43 percent of 70 females with bladder exstrophy also had associated reproductive tract anomalies. The urethra and vagina are typically short and the vaginal orifice is frequently stenotic and displaced anteriorly. The clitoris is duplicated or bifid, and the labia, mons pubis, and clitoris are divergent. The uterus, fallopian tubes, and ovaries are typically normal except for occasional mÃ¼llerian duct fusion defects.

Treatment

Reconstruction of the female genitalia presents a less complex problem than that of the male. Surgical functional closure is currently performed in the first 3 years of life as a staged surgical procedure. Generally, the bladder is closed first, followed by bladder neck reconstruction, and subsequent epispadias repair. Approximation of the clitoral halves in the sparsely hair-bearing skin of the mons pubis provides satisfactory cosmetic restoration (Damario, 1994; Dees, 1949). Vaginal dilatation or vaginoplasty may be required to allow satisfactory intercourse in the mature female (Jones, 1973). Long term, the defective pelvic floor may predispose women to uterine prolapse, making uterine suspension necessary (Gearhart, 1992).

DEFECTS OF THE CLITORIS

Clitoral Anomalies

Congenital abnormalities of the clitoris are unusual, but include clitoral duplication as well as excess androgen exposure leading to clitoral enlargement. Clitoral duplication, also known as *bifid clitoris* , usually develops in association with exstrophy or epispadias. The disorder is rare, with an incidence of 1 in 480,000 females (Elder, 1992).

The clitoris may also be affected by epispadias. In those with epispadias but without bladder extrophy, visibly apparent anomalies include a widened, patulous urethra; absent or bifid clitoris; nonfused labial folds (majora and minora); and flattened mons pubis. Female epispadias can be divided into three typesâ€” vestibular, subsymphyseal, and retrosymphysealâ€"which are differentiated by the type of urethral involvement (Schey, 1980). The vestibular type is an abnormality affecting only the distal urethra. The subsymphyseal type has a urethral abnormality present from its midportion (just beneath the symphysis) and extending distally. The retrosymphyseal designation describes an abnormality beginning at the proximal urethra and extending to the bladder neck. The most distal defect (vestibular type) is generally only an anatomic abnormality. In contrast, the likelihood of associated functional loss of sphincter control and incontinence increases considerably if the abnormality begins more proximally. The correlation of abnormal sphincter function with the degree of urethral abnormality is not absolute, however. Occasionally, patients with a mild form may be continent, but some degree of chronic wetness is common.

Most female patients with epispadias also have other serious physical disabilities. Incontinence causes perineal skin erosion and uriniferous odor. Vertebral abnormalities and diastases of the pubic symphysis are also commonly associated.

Mild degrees of abnormality, not associated with incontinence, may require only vulvoplasty. Those anomalies of the urethra or bladder or both associated with any degree of incontinence, however, need surgical correction. For this purpose, urethroplasty as well as Burch and Marshall-Marchetti-Kranz colposuspension procedures have all been employed. Correction of this anomaly is usually successful. Vesicoureteral reflux, if persistent after correction, however, requires ureteral reimplantation.

Another clitoral anomaly is the female phallic urethra and is found in association with a persistent cloaca (Sotolongo, 1983). The phallic urethra opens at the tip of the clitoris. This anomaly affects 4 to 8 percent of girls with persistent cloaca and has been described in association with embryonic exposure to cocaine (Karlin, 1989).

Clitoromegaly

Finally, clitoromegaly noted at birth is suggestive of fetal exposure to excessive androgens. Clitoromegaly is defined as a clitoral index greater than 10 mm^2 . Clitoral index is determined by the glans length times the width. Early androgen exposure leads to fusion of the labioscrotal folds and findings of a single perineal opening, the urogenital sinus. The labia display a rugated, scrotum-like appearance. A gonad in the groin or labia majora, however, should raise the concern of male pseudohermaphroditism.

In premature neonates, the clitoris may appear large normally, but it does not change in size and appears to regress as the infant grows. Other causes of clitoromegaly include breech presentation with vulvar swelling, chronic severe vulvovaginitis, and neurofibromatosis (Dershwitz, 1984; Greer, 1981).

Adult women with exposure to androgen excess may also present with some degree of clitoromegaly. The normal adult clitoris is generally 1 to 1.5 cm long and 0.5 cm wide in the nonerect state. Virilization of the female from excess levels of androgen may result in a variety of physical changes including not only clitoral enlargement, but also hirsutism, acne, oily skin, deepening of the voice, temporal balding, increase in muscle mass, and decrease in breast size.

LABIAL FUSION

Fusion of the labia majora is a commonly acquired defect of the labia. It is typically found in young neonates or prepubertal girls when the labia and vagina are not adequately estrogenized. This fusion can range from a thin filmy adhesion to a dense scar and is discussed more fully in Chapter 14, Labial Adhesion (Reynolds, 1998).

HYMENEAL DEFECTS

Description and Patient Presentation

The hymen is the membranous vestige of the junction between the sinovaginal bulbs and the urogenital sinus (see Fig. 18-4C). It generally becomes perforate or patent during fetal life to establish a connection between the vaginal lumen and the perineum. A variety of hymeneal abnormalities may exist as shown in Figure 18-10, such as microperforate, septate, cribriform, and imperforate hymen (Breech, 1999). Imperforate hymen is due to complete failure of the inferior end of the vaginal plate to canalize and is noted in approximately 1 in 2,000 females (Parazzini, 1990). Although most cases occur sporadically, cases of imperforate hymen involving multiple family members have been reported (Lim, 2003; Stelling 2000; Usta, 1993).

If the hymen is imperforate, mucus and blood from endometrial sloughing accumulate in the vagina. In infants, the obstructed vagina may distend from mucus accumulation, a condition termed *hydromucocolpos* . More commonly, however, adolescents present after menarche and menstrual blood trapped in the vagina behind the imperforate hymenâ€"*hematocolpos* â€"may create a bluish bulge at the introitus. With cyclic menstruation, the vaginal canal becomes greatly distended, and the cervix may begin to dilate and allow formation of a hematometra and hematosalpinx. Cyclic pain, amenorrhea, abdominal pain mimicking acute abdomen, and difficulty with urination or defecation may be present (Bakos, 1999). Retrograde menstruation may lead to the development of endometriosis. Other obstructive reproductive tract anomalies that are located more cephalad, such as transverse vaginal septum, may present similarly. The associated vulvar distension, however, uniquely suggests imperforate hymen.

Treatment of Hymenal Defects

Patients with microperforate, cribiform, or septate hymen will typically present with menstrual irregularities or with difficulty in tampon placement or intercourse. Repair of imperforate or microperforate hymen may be accomplished at essentially any time the diagnosis is made and is illustrated in Section 41-5, Hymenectomy. Breech and Laufer (1999) advocate repair when the tissues are under the influence of estrogen stimulation, either in infancy or after thelarche, but before menarche. This timing avoids the formation of hematocolpos and hematometra. Laparoscopy can be performed at the time of excision of an imperforate hymen to determine the presence of endometriosis. Clinicians should avoid needle aspiration of a hematocolpos for diagnosis or treatment. This may seed the retained blood with bacteria and place a patient at risk of infection. Moreover, recurrent hematocolpos secondary to inadequate drainage is common following needle aspiration alone.

Hymeneal cysts must be differentiated from an imperforate hymen with hydrocolopos (Nazir, 2006). These cysts typically have an opening and may regress spontaneously. They may also be treated by incision and drainage. Simple puncture has also been successfully performed.

TRANSVERSE VAGINAL SEPTUM

Description and Patient Presentation

Vertical fusion refers to complete cavitation of the vaginal plate between the sinovaginal bulbs and uterovaginal canal. Transverse vaginal septum may be caused by a failure of this process (see Fig. 18-5). The anomaly is uncommon, and Banerjee (1998) reported an incidence of 1 in 70,000 females. The septum may be obstructive, with accumulation of mucus or menstrual blood, or may be non-obstructive, allowing for egress of mucus and blood.

Transverse vaginal septum can develop at any level within the vagina but is more common in the upper portion, that is, at the junction between the sinovaginal plate and the caudal end of the fused mÃ¼llerian ducts (see Fig. 18-4). In a series reported by Rock (1982), 46 percent of septa were located in the upper vagina, 35 percent in the middle, and 19 percent in the lower portion of the vagina. The thickness of the septum may be variable, and thicker septa tend to be located nearer the cervix. Typically, a septum is thin (average thickness of 1 cm), but Rock (1982) reported septal thicknesses of 5 to 6 cm.

In neonates and infants, obstructive transverse vaginal septum has been associated with fluid and mucus collection in the upper vagina, resulting in a mass that that may be large enough to compress abdominal or pelvic organs (Adaletli, 2007). It has been reported to limit diaphragmatic movement, and neonatal deaths have been reported. In addition, pyomucocolopos, pyometria, and pyosalpinges may develop from ascension of vaginal or perineal bacteria through small perforations within the septum (Breech, 1999). In contrast to other defects of the mÃ¼llerian ducts, transverse vaginal septum is fortunately associated with few urologic abnormalities.

Patients with obstructive transverse vaginal septum usually present during adolescence with cyclic lower abdominal pain, amenorrhea, and gradual development of a central pelvic mass. Those with nonobstructive transverse vaginal septum will typically complain of abnormal menstrual flow, pain with intercourse, difficulty in placing or removing tampons, or obstructed labor.

Diagnosis and Treatment

The diagnosis is suspected when an abdominal or pelvic mass is palpated or when a foreshortened vagina and inability to identify the cervix is encountered. Diagnosis is confirmed by either sonography or magnetic resonance (MR) imaging. Magnetic resonance imaging is most helpful prior to surgery to determine the thickness and depth of the transverse septum (Fig. 18-11). In addition, MR imaging may identify if a cervix is present, thereby differentiating a high vaginal septum from cervical agenesis.

FIGURE 18-11

Magnetic resonance image of complete low transverse septum with obstruction. Marked hematocolpos is identified (arrows) in this 13-year-old female. The relatively low signal intensity on T2-weighted imaging is consistent with subacute blood. The uterus is seen above the hematocolpos. *(Courtesy of Dr. Doug Sims.)*

Surgical repair is dependent upon septal thickness and skin grafts may occasionally be necessary to cover a defect left by excision of very thick septa. Smaller septa may be approached by excision with an end-to-end anastomosis of the upper to the lower vagina as described by Suidan (1979) (see Section 41-11, Transverse Vaginal Septum Excision). Sanfilippo (1986) recommends laparoscopy at the time of surgical therapy for transverse vaginal septum because of the high rate of endometriosis seen in association with outflow tract obstruction.

As an alternative to excision with end-to-end anastomosis, Garcia (1967) reported a Z-plasty technique that may minimize scar formation. Wierrani (2003) reported using Garcia's procedure in 13 patients. Postoperative scarring and resulting vaginal contracture did not develop. Postoperatively, patients were sexually active and reported satisfaction with sexual function.

LONGITUDINAL VAGINAL SEPTUM

A longitudinal vaginal septum results from defective lateral fusion and incomplete reabsorption of the paired mÃ¼llerian ducts. These septa are generally seen with partial or complete duplication of the cervix and uterus. Individuals complain of difficulty with intercourse or with complaints of vaginal bleeding despite tampon placement. The latter results from placement of the tampon into only one of the duplicated vaginas. The nonobstructed form can be managed conservatively unless dyspareunia develops. Surgical treatment includes resection of the longitudinal septum.

In addition, an obstructive variety of longitudinal vaginal septum can develop (Fig. 18-12). Typically the patient presents in adolescence with normal menarche, but reports worsening monthly unilateral vaginal and pelvic pain (Carlson, 1992). On examination, a patent vagina and cervix is noted, but a unilateral vaginal and pelvic mass can be seen. The mass represents obstruction of one of the hemivaginas associated with uterine duplication. Surgical correction consists of wide excision of the obstructing septum. Joki-Erkkila and Heinonen (2003) followed 26 females after surgical repair of obstructive outflow tract anomalies. They found a high rate of vaginal stricture requiring re-operation, as well as dysfunctional uterine bleeding, dyspareunia, and dysmenorrhea. Ipsilateral renal agenesis is extremely common with this malformation.

GARTNER DUCT CYSTS

Gartner duct cysts are vestigial remnants of the wolffian ducts, and these mesonephric cysts are most commonly found on the cephalad, lateral wall of the vagina (see Fig. 18-2). The cysts are usually 1 to 5 cm in size and are typically found only incidentally during pelvic examination. A small asymptomatic Gartner duct cyst may be followed conservatively. Deppisch (1975) described 25 cases of symptomatic vaginal cysts. They reported a wide range of symptoms, including dyspareunia, vaginal pain, difficulty with tampon use, urinary symptoms, and palpable mass.

Symptomatic cysts may be treated by operative excision. Occasionally, these cysts may become infected, and if intervention is required during the acute phase, marsupialization of the cyst is preferred. Of note, excision of a vaginal cysts may be much more difficult and time consuming than anticipated, as some may extend up into the broad ligament and anatomically approximate the distal course of the ureter.

MÃ¼LLERIAN ANOMALIES

Incidence and Classification

Anomalies of the uterus may be congenital or acquired and typically present with abnormalities of the menstrual cycle, pelvic pain, infertility, or pregnancy wastage. The true incidence of congenital mÃ¼llerian anomalies, of which uterine malformations constitute the majority, is unknown. Most cases are diagnosed during evaluation for obstetric or gynecologic problems, but in the absence of

symptoms, most anomalies go undiagnosed. Because nearly 57 percent of women with uterine defects have successful fertility and pregnancy, the true incidence of congenital mÃ¼llerian defects may be significantly understated. Simon and colleagues (1991) found uterine anomalies in 3 percent of 679 fertile women undergoing laparoscopic tubal sterilization. Nahum (1998) found that the prevalence of uterine anomalies in the general population was 1 in 201 women or 0.5 percent.

Anatomic uterine defects have long been recognized as a cause of obstetric complications. Recurrent pregnancy loss, preterm labor, abnormal fetal presentation, and prematurity constitute the major reproductive problems encountered with developmental or acquired uterine malformations. MÃ¼llerian defects are also associated with renal anomalies in 30 to 50 percent of cases, ranging from renal agenesis and severe hypoplasia to ectopic or duplicate ureters (Sharara, 1998).

Congenital anomalies of the reproductive tract present a diagnostic challenge because of the variety of morphologic presentations. The apparent complexity can be greatly simplified by understanding the critical embryonic events that occur in normal mÃ¼llerian development. Various classification schemes for anomalies of the female reproductive tract exist, but the most common system was proposed by Buttram and Gibbons (1979) and adapted by the American Society of Reproductive Medicine (American Fertility Society, 1988) (Table 18-2). Within this system, six categories are used to classify similar embryonic developmental defects (Fig. 18-13).

Table 18-2 Classification of MÃ¼llerian Anomalies[a]
I. Segmental mÃ¼llerian hypoplasia or agenesis a. Vaginal b. Cervical c. Uterine d. Tubal e. Combined
II. Unicornuate uterus a. Rudimentary horn with cavity, communicating to unicornuate uterus b. Rudimentary horn with cavity, not communicating to unicornuate uterus c. Rudimentary horn with no cavity d. Unicornuate uterus without a rudimentary horn
III. Uterine didelphys
IV. Bicornuate uterus a. Complete bifurcation (bicollis) b. Partial bifurcation (unicollis)
V. Septate uterus a. Complete septation b. Partial septation
VI. Arcuate uterus
VII. Diethylstilbestrol-related anomalies

Segmental MÃ¼llerian Hypoplasia or Agenesis

PATHOPHYSIOLOGY AND PATIENT PRESENTATION

Some form of mÃ¼llerian hypoplasia or agenesis affects one in every 4,000 to 5,000 females and is a common cause of primary amenorrhea (Patton, 1994). Agenesis results from a defect in the development of the lower portion of the mÃ¼llerian ducts and usually leads to variable absence of the uterus, cervix, and/or upper part of the vagina (Fig. 18-13A).

VAGINAL AGENESIS

Females with vaginal atresia lack the lower portion of the vagina, but otherwise have normal external genitalia. The embryonic origin of this condition is presumed to involve failure of the urogenital sinus to contribute its expected caudal portion of the vagina (Simpson, 1999). As a result, the lower portion of the vagina, usually one fifth to one third of the total length, is replaced by 2 to 3 cm of fibrous tissue. In some individuals, however, vaginal atresia may extend to near the cervix.

Since most women with vaginal atresia have normal external genitalia and upper reproductive tract organs, this condition does not often become apparent until the time of expected menarche. Adolescents generally present shortly after physiologic menarche with cyclic pelvic pain due to hematocolpos or hematometra. On physical examination, normal breast and pubic hair development is present. The perineum is usually normal, with normal secondary sex characteristics with a hymeneal ring and beyond the ring, a vaginal dimple or small pouch. A rectoabdominal examination confirms the presence of midline structures. Additionally, sonographic or MR imaging will display upper reproductive tract organs. Of these, MR imaging is a more accurate diagnostic tool, as the length of the atresia, the amount of upper vaginal dilatation, and the presence or absence of a cervix can be identified. Laparoscopy, however, is necessary for diagnosis when the anatomy cannot be fully evaluated with radiographic studies. For example, Economy and associates (1998) reported that MR imaging has only 31-percent sensitivity for the detection of uterine structures in patients with vaginal agenesis. About one third of women with vaginal atresia have associated urologic abnormalities.

Vaginal atresia is distinct in clinical and embryonic characteristics from transverse vaginal septum. In patients with transverse vaginal septum there is a well-developed vagina in which a thick intervening septum separates the lower from the upper vagina. Conversely, in those with vaginal atresia, fibrous tissue develops in place of the vagina. In some, nearly the entire span beginning at the perineum and extending cephalad to the cervix may be fibrotic. Identification of the cervix in such cases distinguishes

vaginal atresia from mÃ¼llerian agenesis.

MÃ¼LLERIAN AGENESIS

A more common presentation of vaginal atresia is congenital absence of both the uterus and vagina, which is also referred to as *mÃ¼llerian aplasia* , *mÃ¼llerian agenesis* , or *Mayer-Rokitansky-KÃ¼ster-Hauser syndrome* . In classic mÃ¼llerian agenesis, patients have a shallow vaginal pouch, only measuring up to 1.5 inches deep. In addition, the uterus, cervix, and upper part of the vagina are absent. Typically, a portion of the distal fallopian tubes are present. In addition, normal ovaries are present, given their separate embryonic origin. Most patients with mÃ¼llerian agenesis have only small rudimentary mÃ¼llerian bulbs without endometrial activity. However, in 2 to 7 percent of women with this condition, active endometrium develops and patients typically present with cyclic abdominal pain (American College of Obstetricians and Gynecologists, 2002). Surgical excision of symptomatic rudimentary bulbs is required. With mÃ¼llerian agenesis, traditional conception is impossible, but pregnancy may be achieved using sophisticated technology involving oocyte retrieval, fertilization, and implantation into a surrogate. Evaluation for associated congenital renal or other skeletal anomalies is essential in individuals with mÃ¼llerian hypoplasia or agenesis. Approximately 15 percent of women with uterine agenesis also have defects of the urinary system, and 12 percent may have scoliosis.

TREATMENT

One treatment goal for most of these women is creation of a functional vagina. This may be accomplished conservatively or surgically. There are several conservative approaches, and each attempts to progressively invaginate the vaginal dimple to create a canal of adequate size. Graduated hard glass dilators were initially recommended by Frank (1938). Ingram (1981) modified the Frank method by affixing the dilators to a bicycle seat mounted upon a stool. This affords patients hand mobility for other activities during the 30 minutes to 2 hours spent each day for passive dilation (American College of Obstetricians and Gynecologists, 2002). Currently, firm silicon dilators are available through several medical vendors. A vagina may also be created with repeated coitus. Overall, vaginal dilatation techniques are successful in forming a functional vaginal in as many as 90 percent of cases (Croak, 2003; Roberts, 2001).

Surgical procedures are seen by many as a more immediate solution to creation of a neovagina, and several methods have been reported. The method used most commonly by gynecologists is the McIndoe vaginoplasty (McIndoe, 1950). As illustrated in Section 41-12, McIndoe Procedure, a canal is created within the connective tissue between the bladder and rectum. A split-thickness skin graft obtained from the patient's buttocks or thigh is then used to line the neovagina. Strickland (1993) reported excellent function and patient satisfaction.

Modifications of the McIndoe procedure include the use of human amnion, peritoneum, buccal mucosa, and Interceed absorbable adhesion barrier (Ethicon, Somerville, NJ) as neovaginal linings (Ashworth, 1986; Lin, 2003; Ozgenel, 2003; Motoyama, 2003). For example, Jackson and Rosenblatt (1994) described four cases of vaginoplasty using Interceed absorbable adhesion barrier. This method is less invasive than acquiring a skin graft, but complete epithelialization of the new vaginal wall requires 3 to 6 months. Noguchi and others (2004) reported the successful creation of a neovagina using artificial dermis (atelocollagen sponge) and the use of postoperative recombinant basic fibroblast growth factor spray to accelerate epithelialization. Squamous epithelialization of the vaginal epithelium was confirmed by histologic examination at 50 days after the operation, and no stenosis was observed.

Similarly, cutaneous or musculocutaneous flaps have been employed to line the neovagina. For example, the Williams vaginoplasty creates a vaginal pouch using labial skin flaps (Williams, 1964). This may not be as acceptable to young women, as it creates an awkward angle for sexual intercourse and a less cosmetically pleasing appearance.

All of these methods require a commitment to scheduled postoperative dilatation to avoid significant vaginal stricture (Breech, 1999). Accordingly, these procedures should be considered only if the patient is mature and willing to adhere to a postoperative regimen of regular intercourse or manual dilatation with dilators.

To avoid this necessity, pediatric surgeons more frequently use a segment of bowel to create the vagina. These colpoplasties most commonly use sigmoidal or ileal segments and require laparotomy and bowel anastomosis. Moreover, many patients complain of a persistent vaginal discharge from the gastrointestinal mucosa. In contrast, the Vecchietti procedure uses an initial abdominal surgery to place an apparatus for passive vaginal dilatation. The apparatus is a sphere and two guide wires. The sphere, attached

to the two wires, is placed in the vaginal dimple. The wires are guided through the potential neovaginal space to exit on the anterior abdominal wall. From the anterior abdominal wall, external pressure is exerted, which is increased daily to allow the blind vaginal pouch to be stretched by the sphere (Vecchietti, 1965).

Unicornuate Uterus

Arrested or defective development of only one of the mÃ¼llerian ducts results in a unicornuate uterus (Fig. 18-13B). The incidence of unicornuate uterus, as diagnosed by hysterosalpingography (HSG), in a series of 1,160 uterine anomalies was 14 percent (Zanetti, 1978). This was likely an underestimation, because HSG cannot be used to identify noncommunicating rudimentary horns, by far the most common anomaly.

Women with a unicornuate uterus have an increased incidence of infertility, endometriosis, and dysmenorrhea (Fedele, 1987; Heinonen, 1983). Reproductive performance of the unicornuate uterus is significantly impaired, and fetal survival rates are poor. Akar (2005) reported a live birth rate of only 29 percent in women with unicornuate uterus. A substantial percentage of these pregnancies, about 45 percent, are lost within the first two trimesters. Premature delivery is also a risk, occurring in 20 percent of all pregnancies in patients with this defect. Obstetric complications, such as breech presentation, fetal growth restriction, dysfunctional labor, and cesarean delivery are also more common (Acien, 1993).

The pathogenesis of pregnancy loss associated with unicornuate uterus is incompletely understood, but reduced uterine capacity that does not permit adequate gestational growth and development is a possible mechanism. In the unicornuate uterus, fetal growth restriction appears to be correlated with vascular anomalies in the distribution of the uterine artery (Burchell, 1978). These observations suggest that congenital alterations in blood flow mediate uterine and placental growth disturbances. Moreover, a relative cervical incompetence may contribute to the risk for premature delivery and late-trimester abortion. Accordingly, a unicornuate uterus should be suspected in any woman with a history of pregnancy loss, premature delivery, or abnormal fetal lie.

DIAGNOSIS AND MANAGEMENT

On physical examination, the uterus is often markedly deviated, reflecting the developmental failure of one of the mÃ¼llerian ducts. Hysterosalpingography, combined with sonography or MR imaging, is a key study in the evaluation. Typically, HSG films show a deviated banana-shaped cavity with a single fallopian tube. Rudimentary development of a uterine horn in association with a unicornuate uterus is best confirmed by sonography. This modality is sufficiently accurate and may be more reliable than laparoscopy in determining whether rudimentary structures are cavitary and thus contain endometrial tissue. Three-dimensional transvaginal sonography has also been used reliably in an office setting to diagnose and classify mÃ¼llerian anomalies (Raga, 1996).

Data from the combined series of 38 patients reported by Buttram and Gibbons (1979) and Fedele and associates (1987) indicate that approximately 65 percent of unicornuate uteri have an associated rudimentary horn. Thirty-one percent contained endometrial tissue, and one half of these communicated with the main uterine cavity. A rudimentary horn without an endometrial cavity was present in 34 percent of cases.

Pregnancies in the noncommunicating rudimentary horn are associated with a high rate of uterine rupture. These pregnancies are thought to occur by the intra-abdominal transit of sperm from the normal horn. Rolen and associates (1966) reported that uterine rupture occurred prior to 20 weeks in most of 70 rudimentary horn pregnancies. Nahum (2002) reviewed the literature from 1900 to 1999 and identified reports of 588 such pregnancies. In 419 cases, the communication status was known and half of these had uterine rupture, 80 percent before the third trimester. Eighty-five percent of the horns were of the noncommunicating type, and the rupture rate in these was 85 percent. Fetal survival was 6 percent overall in the 588 cases. More liberal use of sonography and MR imaging may result in an earlier diagnosis of cavitary rudimentary horns. Because of the high risk for maternal morbidity secondary to rupture with pregnancy and intraperitoneal hemorrhage, excision of a cavitary rudimentary horn is indicated whenever it is identified (Heinonen, 1997). To that end, Dicker (1998) reported the laparoscopic removal of rudimentary horn pregnancy. If the rudimentary horn is nonfunctioning (solid, with no functional endometrium) removal is not routinely recommended, as no adverse effect on reproductive outcome has been reported. Salpingectomy or salpingo-oophorectomy on the side with the rudimentary horn, however, has been suggested to prevent ectopic pregnancy in women with a unicornuate uterus, although in the series of Buttram, the ectopic pregnancy risk was low.

Uterine Didelphys

A didelphic uterus results when there is failed fusion of the paired mÃ¼llerian ducts (Fig. 18-13C). This anomaly is characterized by the presence of two endometrial cavities, each with a uterine cervix. A longitudinal vaginal septum runs between the two cervices in most cases. Heinonen (1984) reported that all 26 women with uterine didelphys in his series had a longitudinal vaginal septum. Occasionally, one hemivagina is obstructed by an oblique or transverse vaginal septum (Fig. 18-12A) (Hinckley, 2003).

Uterine didelphys should be suspected if a longitudinal vaginal septum or if two separate cervices are discovered. This anomaly may be identified during sonography (see Fig. 2-19). To confirm the diagnosis, HSG is recommended to identify the possibility of communication between the uteri (Fig. 19-7C).

Of all the major uterine malformations, the didelphic uterus has the best reproductive prognosis. Specifically, when compared with the unicornuate uterus, the potential for uterine growth and capacity appears similar. However, compared with a unicornuate uterus, uterine didelphys probably has an improved blood supply through collateral connections between the two horns. Alternatively, improved fetal survival may be secondary to earlier diagnosis of the uterine didelphys (because of the vaginal septum), which favors earlier and more intensive prenatal care (Patton, 1994). Heinonen (2000) surveilled 36 women with uterus didelphys. He found that 34 out of 36 women (94 percent) who wanted to conceive had at least one pregnancy, and they produced 71 pregnancies. Of these pregnancies, 21 percent were spontaneously aborted and 2 percent were ectopic. The rate for fetal survival was 75 percent; for prematurity, 24 percent; for fetal growth restriction, 11 percent; for perinatal mortality, 5 percent; and for cesarean delivery, 84 percent. Pregnancies located more commonly (76 percent) in the right uterus than in the left. Because the spontaneous abortion rate mirrors that of women with normal uterine cavities, surgical procedures in response to pregnancy loss are rarely indicated. Thus, surgery should be reserved for highly selected women in whom repeated late-trimester losses or premature delivery has occurred with no other apparent etiology.

Bicornuate Uterus

PATHOPHYSIOLOGY AND REPRODUCTIVE OUTCOME

A bicornuate uterus is caused by incomplete lateral fusion of the mÃ¼llerian ducts. It is characterized by two separate but communicating endometrial cavities and a single uterine cervix. Failure of fusion may extend to the cervix, resulting in a complete bicornuate uterus, or may be partial, causing a milder abnormality (Fig. 18-13D). Several studies suggest that women with a bicornuate uterus can expect reasonable success in delivering a living child (about 60 percent). Rock (1977) reported that a bicornuate uterus was present in 55 percent of women with an anomalous uterus who had a satisfactory reproductive history. Only 14 percent of women with poor reproductive performance had a bicornuate uterus. As with many uterine anomalies, premature delivery is a substantial obstetric risk. Heinonen and colleagues (1982) reported a 28-percent abortion rate and a 20-percent incidence of premature labor in women with a partial bicornuate uterus. Women with a complete bicornuate uterus had a 66-percent incidence of preterm delivery and a lower fetal survival rate.

DIAGNOSIS AND TREATMENT

Hysterosalpingography is the initial diagnostic step in evaluating a possible bicornuate uterus. Classically, the uterine horns show a marked divergence, but various morphologic results are possible (see Fig. 19-7A). Because HSG may not accurately distinguish a bicornuate from a septate uterus, additional testing is necessary to make a definitive diagnosis. For example, sonography has been used successfully to differentiate the two. Malini (1984) reviewed 50 cases of uterine anomalies and compared sonographic findings with those obtained by HSG and laparoscopy. Sonography was confirmatory or diagnostic of the suspected anomaly in most cases (88 percent). Moreover, the diagnostic accuracy of sonography may be improved when coupled with HSG. Reuter and co-workers (1989) reported a diagnostic accuracy of 90 percent when the two techniques were used. A potentially more accurate method uses MR imaging (see Fig. 2-27). Pellerito (1992) evaluated uterine anomalies by MR imaging, and correctly identified all of 24 bicornuate uteri. Although fundal contour and septal conformation can be accurately visualized by MR imaging, its high cost precludes its use in all cases. Thus, sonography and HSG seem to be acceptable imaging techniques in the initial investigation. When the presumptive diagnosis is a septate uterus, laparoscopy is indicated for a definitive diagnosis and before hysteroscopic resection of the septum is initiated.

Surgical reconstruction of the bicornuate uterus has been advocated in women with multiple spontaneous abortions and in whom no other causative factors are identified. Strassman (1952) described the surgical technique that was designed to unify equal-sized endometrial cavities (Fig. 18-14B). Reproductive outcome after unification generally has been good. In 289 women, preoperative pregnancy loss was more than 70 percent. Following surgery, more than 85 percent of pregnancies ended in delivery of a viable infant. The actual benefit of metroplasty for a bicornuate uterus, however, has not been tested in a controlled clinical series. As in surgery for uterine didelphys, metroplasty should be reserved for women in whom recurrent pregnancy loss occurs with no other identifiable cause. Cesarean delivery is indicated following metroplasty to avert uterine rupture during labor.

Septate Uterus

PATHOPHYSIOLOGY AND REPRODUCTIVE OUTCOME

After lateral fusion of the mÃ¼llerian ducts, failure of their medial segments to regress can create a permanent septum within the uterine cavity. Its contours can vary widely and depends on the amount of persistent midline tissue. For example, the septum can project minimally from the uterine fundus or can extend completely to the cervical os (Fig. 18-13E). Moreover, septa can develop segmentally, resulting in partial communications of the partitioned uterus (Patton, 1994). The histologic structure of septa ranges from fibrous to fibromuscular.

The true incidence of these anomalies is not known because they are usually only detected in women with obstetric complications.

Although this defect does not predispose to increased rates of preterm labor or cesarean delivery, septate uterus is associated with a marked increase in spontaneous abortion (Heinonen, 2006). Woelfer and colleagues (2001) reported a first-trimester spontaneous abortion rate for septate uterus of 42 percent. Moreover, early pregnancy loss is significantly more common with a septate than with a bicornuate uterus (Proctor, 2003). For example, Buttram and Gibbons (1979) noted pregnancy loss rates in the first 20 weeks of 70 percent for bicornuate uterus compared with 88 percent for septate uteri.

This high pregnancy wastage likely results from partial or complete implantation on the largely avascular septum. This diminished blood supply, in combination with distortion of the uterine cavity and associated cervical or endometrial abnormalities, has been implicated. Based on operative experience for septal defects, the blood supply to the fibromuscular septum appears markedly reduced compared with that of normal myometrium. Altered patterns of vascularity in specimens of septal mucosa observed by Candiani and associates (1990) also reinforces the idea that pregnancy loss may be related to impaired embryo growth associated with septal implantation.

In addition to spontaneous abortion, septate uterus may infrequently cause fetal malformation. Heinonen (1999) described three newborns with a limb-reduction defect born to women with septate uterus.

DIAGNOSIS AND TREATMENT

Diagnosis of the septate uterus follows guidelines established for the bicornuate uterus and includes HSG and sonography (see Fig. 19-5B). Prior to widespread use of minimally invasive hysteroscopic procedures, abdominal metroplasty for septate uterus was shown to dramatically decrease fetal wastage and ultimately improve fetal survival (Figs. 18-14A and 18-14C) (Blum, 1977; Rock, 1977). Two main disadvantages to metroplasty include the recommendation for cesarean delivery to prevent uterine rupture, and the high rate of postoperative pelvic adhesion formation and subsequent infertility. A review by Bennet (1987) indicated a 30-percent incidence of infertility after abdominal metroplasty, but others have reported normal postoperative fecundity rates.

Currently, hysteroscopic septum resection is an effective and safe alternative to treat women with septate uterus (Fig. 18-15) (see Section 41-39, Septoplasty). Typically, operative hysteroscopy is combined with laparoscopic surveillance to reduce the risk of uterine perforation. After the initial case reports by Chervenak and Neuwirth (1981), many investigators have confirmed satisfactory live birth rates with the procedure (Daly, 1983; DeCherney, 1983; Israel, 1984). In a retrospective review, Fayez (1986) evaluated reproductive outcome in women who had either an abdominal metroplasty or hysteroscopic septoplasty. In this comparative analysis, an 87-percent live birth rate was reported in the hysteroscopic group, compared with a 70-percent rate in the abdominal group. Similarly, Daly and associates (1989) reported impressive results after hysteroscopic surgery. In 51 women, 47 had a total of 79 pregnancies. Only 6 percent gave birth prematurely, and 70 percent delivered at term. Moreover, proponents of the hysteroscopic procedure indicate that it reduces the risk of pelvic adhesions, shortens postoperative convalescence, lessens morbidity, and obviates the mandate for cesarean delivery (Patton, 1994).

Arcuate Uterus

An arcuate uterus is only a mild deviation from the normally developed uterus (Fig. 18-13F). Some clinicians report no impact on reproductive outcomes. Conversely, Woelfer and colleagues (2001) found excessive second-trimester losses and preterm labor. Surgical resection is indicated only if excessive loss is encountered and other etiologies for recurrent spontaneous abortion have been excluded.

ACQUIRED UTERINE DEFECTS

Defects in uterine structure and function may develop from exposure to diethylstilbestrol (DES); from intrauterine adhesion formation, termed *Asherman syndrome;* or from neoplastic growth, such as leiomyomas. These acquired uterine defects are recognized as contributors to pregnancy loss, and the spectrum of reproductive difficulties seen with these acquired defects mirrors that seen with congenital anomalies.

Diethylstilbestrol-Induced Reproductive Tract Abnormalities

REPRODUCTIVE TRACT FINDINGS

Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed for an estimated 3 million pregnant women in the United States from the late 1940s through the early 1960s. Early reports claimed that the drug was useful in treating abortion, preeclampsia, diabetes, and preterm labor. It was unfortunately ineffective for these indications. Almost 20 years later, Herbst and co-workers (1971) found that DES exposure in utero was linked to the later development of vaginal clear cell adenocarcinoma in exposed female fetuses. The risk of this vaginal malignancy is about 1 per 1,000 exposed daughters. Subsequently, it was established that these daughters also had increased risks of developing cervical intraepithelial neoplasia as well as small cell cervical carcinoma (Herbst, 2000).

Additionally about one third have vaginal adenosis. During normal development, the vagina is originally lined by a glandular epithelium derived from the mÃ¼llerian ducts. By the end of the second trimester, this layer is replaced by squamous epithelium extending up from the urogenital sinus. Failure of the squamous epithelium to completely line the vagina is termed adenosis. Its clinical appearance is varied and may appear red, punctuate, and granular. Symptoms most often reported include vaginal irritation, discharge, and metrorrhagia, in particular, postcoital bleeding. Moreover, adenosis is noteworthy for its frequent association with vaginal clear cell adenocarcinoma.

In addition to carcinogenesis, several non-neoplastic abnormalities of the genitourinary tract following DES exposure in utero have become apparent. For example, as many as one fourth of women exposed to DES in utero have identifiable structural variations in the cervix and vagina. These include transverse septa, circumferential ridges involving the vagina and cervix, and cervical collars (see Fig. 32-7). Women with cervicovaginal abnormalities are more likely to have uterine anomalies, and half of all exposed women have uterine cavity anomalies evident on HSG. Significantly smaller uterine cavities, shortened upper uterine segments, and T-shaped and irregular cavities have been described (Fig. 18-13G) (Barranger, 2002). Additionally, abnormalities of the fallopian tubes have been noted, including shortened and narrowed dimensions and absence of fimbria. Hysterosalpingography remains the primary imaging procedure for the identification of these anomalies.

Males who were exposed to DES in utero also have structural abnormalities and cryptorchidism, testicular hypoplasia, microphallus, and hypospadias have been reported (Hernandez-Diaz, 2002). Moreover, Klip and colleagues (2002) provided evidence suggesting a transgeneration effect, in which male fetuses conceived by daughters of DES-exposed women have increased rates of hypospadias.

REPRODUCTIVE OUTCOME

In general, women exposed to DES have impaired conception rates (Goldberg, 1999; Palmer, 2001; Senekjian, 1988). Reduced fertility in these women is poorly understood but is associated with cervical hypoplasia and atresia. Of those who do conceive, the incidence of spontaneous pregnancy loss, ectopic pregnancy, and preterm delivery are increased, again particularly in those with associated structural abnormalities (Goldberg, 1999). For example, Herbst and colleagues (1989) reported the risk of ectopic pregnancy to be 7 percent in DES-exposed women, compared with none in a control group. Tubal anomalies resulting from DES exposure are the most likely cause, but associated decreased uterine size may also be a factor. In contrast, increases in preterm delivery rates probably result from uterine and cervical anomalies (deHaas, 1991; Herbst, 2000). Cervical incompetence is associated with mid-pregnancy losses and preterm delivery in these women (Ludmir, 1987). In 5 of 21 pregnancies, Michaels and co-workers (1989), using serial sonographic examinations, documented preterm cervical effacement and dilatation.

Asherman Syndrome

PATHOPHYSIOLOGY AND CLINICAL FINDINGS

Asherman syndrome is an infrequently found acquired uterine disorder characterized by intrauterine adhesions (see Figs. 16-2 and 41-41.1). Theories concerning the pathogenesis of this intrauterine scarring are based on several clinical observations. Specifically, in a series of 1856 women with Asherman syndrome, 88 percent were associated with postabortal or postpartum uterine curettage, indicating that direct endometrial trauma is a key factor (Schenker, 1982). In addition, occult infection and retained pregnancy tissue may be contributory (Rabau, 1963).

Classically, menstrual disorders and infertility are the presenting hallmarks of Asherman syndrome. Changes in menstrual patterns, such as amenorrhea or hypomenorrhea, are common and found in approximately 75 percent of women with this syndrome. Recent evidence, however, shows that women with Asherman syndrome may also present primarily with pregnancy loss. In their evaluation of 292 women with intrauterine adhesions, Schenker and Margalioth (1982) noted delivery of term pregnancies in only 30 percent of 165 pregnancies. The remainders either were spontaneously aborted (40 percent) or delivered prematurely. Pregnancy loss or prematurity may result from impaired implantation secondary to the intrauterine fibrosis and endometrial inflammation that is frequently observed with this syndrome.

DIAGNOSIS AND TREATMENT

When the syndrome is suspected, HSG is indicated. Of technical note during the procedure, rapid filling of the uterine cavity with

radiopaque contrast media may obscure adhesion detection. For this reason, Patton (1994) suggested using a water-soluble medium, slow incremental injections, image intensification, and multiple views to increase the procedure's sensitivity. Intrauterine adhesions characteristically appear as irregular, angulated filling defects within the uterine cavity (Fig. 18-16). The spectrum of scarring can range from isolated defects to complete obliteration of the uterine cavity. At times, uterine polyps, leiomyomas, air bubbles, and blood clots may masquerade as adhesions. Transvaginal sonography or saline-infusion sonography may help clarify these difficult cases, but a definitive diagnosis requires hysteroscopy (see Fig. 2-18).

FIGURE 18-16

When the diagnosis of Asherman syndrome is confirmed, hysteroscopic lysis of adhesions is the preferred surgical treatment and is described in Section 41-41, Lysis of Intrauterine Adhesions. Prior to the introduction of operative hysteroscopy, dilatation and curettage was employed. Although effective in lysing intrauterine adhesions, this blind procedure unfortunately also injured normal endometrium. In contrast, the direct inspection afforded by hysteroscopy allows precise division of adhesion bands, clear documentation of the location and degree of adhesions, and the results of the operative repair. As with uterine septum resection, laparoscopy may be a necessary adjunct in moderate or severe cases to reduce the risk of perforation and intraperitoneal injury.

Direct comparisons between curettage and hysteroscopy have been difficult because they are based primarily on historic reviews of surgical series. Despite limitations to this type of data analysis, the collective results suggest that hysteroscopic methods are superior. For example, following the use of curettage, Schenker (1982) noted that 69 percent of women delivered at term, 8 percent delivered prematurely, and 10 percent suffered obstetric complications, including placenta accreta. In comparison, using hysteroscopy, Shaffer (1986) reported a similar term pregnancy rate (67 percent), but premature delivery rates of only 2 percent and obstetric complications in 3 percent. March and Israel (1981) reported impressive results after hysteroscopic surgery, with a postoperative term delivery rate of 87 percent. Moreover, reproductive outcome is excellent even when severe intrauterine adhesions are identified. Valle and Sciarra (1988) reported a term delivery rate of 79 percent in 14 women who conceived after surgery, despite severe adhesions. In addition, a 94-percent term delivery rate was observed in this series when mild adhesions

were present.

Uterine Leiomyomas

Uterine leiomyomas are the most common pelvic tumors in women, and accordingly, these acquired uterine defects pose a significant problem in both obstetrics and gynecology. A fuller discussion of the diagnosis and treatment of these growths is found in Chapter 9, Leiomyomas.

CERVICAL DEFECTS

Cervical Agenesis

Because of the common mÃ¼llerian source, women with congenital absence of the cervix typically also lack the upper vagina. The uterus, however, usually develops normally.

These patients initially present similarly to patients with other obstructive anomalies, that is, with primary amenorrhea and cyclic abdominal or pelvic pain. If a functional endometrium is present, a patient may have a distended uterus, and endometriosis may have developed secondary to retrograde menstrual flow. A single midline uterine fundus is the norm, although bilateral hemi-uteri have also been described (Dillon, 1979).

Radiographic studies, sonography, and MR imaging are helpful in evaluating the anatomy. If imaging demonstrates an obstructed uterus, hysterectomy has been recommended by Rock (1984). In contrast, Niver (1980) reported creation of an epithelialized endocervical tract and vagina in three patients. Significant morbidity, including infection, recurrent obstruction, and death due to sepsis, however, has been reported with establishment of such a vaginal-uterine connection by Casey (1997). Alternatively, conservative management with oral contraceptive pills may be used to suppress retrograde menses and possible endometriosis until a patient is ready to evaluate reproduction options. Thus, the uterus may be retained for possible reproductive potential. For example, Thijssen and associates (1990) reported a successful pregnancy using zygote intrafallopian tube transfer in a patient with cervical agenesis.

Cervical Stenosis

Cervical stenosis may result from congenital or acquired conditions and most commonly involves the internal os. Congenital cervical stenosis is likely due to segmental mÃ¼llerian hypoplasia. In contrast, postoperative scarring from cone biopsy, infection, neoplasia, and atrophic or radiation changes can lead to acquired cervical stenosis.

Symptoms of stenosis in menstruating women include dysmenorrhea, abnormal bleeding, amenorrhea, and infertility. Postmenopausal women are usually asymptomatic until there is an accumulation of fluid, exudates, or blood. The terms hydrometra (fluid), pyometra (exudate), or hematometra (blood) are used to describe these conditions and are discussed additionally in Chapter 9, Hematometra. The diagnosis is made on physical examination by an inability to introduce a dilator into the uterine cavity. If the obstruction is complete, a soft, enlarged uterus is palpable.

Management of cervical stenosis involves dilatation of the cervix with dilators of sequentially increasing diameter. Sonographic guidance may be useful to avoid uterine perforation, especially in postmenopausal women. Endometrial sampling is essential in these women to exclude endometrial hyperplasia or cancer.

OVARIAN ANOMALIES

A *supernumerary ovary* is an ectopic ovary that has no connection with the broad, utero-ovarian, or infundibulopelvic ligaments (Wharton, 1959). This rare gynecologic anomaly may be located in the pelvis, retroperitoneum, para-aortic area, colonic mesentery, or omentum. Aberrant migration of part of the gonadal ridge after the incorporation of germ cells describes one theorized schema. Arrest of these migrating germ cells in an ectopic site is followed by inductive formation of the surrounding tissue into ovarian stroma (Printz, 1973). Kuga (1999) described two cases of neonates found to have a supernumerary ovary resembling an omental cyst. Both supernumerary ovaries were detected by antenatal sonography, and the torsed cystic masses were removed by laparoscopy when the infants were 1 month. Mercer (1987) described two cases of supernumerary ovary presenting with adnexal masses that were separated from the ipsilateral ovary. Cystic teratoma and serous cystadenoma of the supernumerary ovary were found.

In contrast, the term *accessory ovary* is used when excess ovarian tissue is noted near a normally placed ovary and is connected to it. Wharton (1959) noted that both accessory ovary and supernumerary ovary were rare, finding approximately 1 case of accessory ovary in 93,000 patients and 1 case of supernumerary ovary in 29,000 autopsies. In Wharton's review, 3 of 4 patients with supernumerary ovary and 5 of 19 patients with accessory ovary had additional congenital defects, most frequently abnormalities of the genitourinary tract.

Unilateral ovarian absence is rare and describes the absence of one ovary, with or without the absence of the fallopian tube. It may result from a congenital malformation (agenesis or aplasia) or from ovarian torsion with necrosis and reabsorption, either antenatally or postnatally (Eustace, 1992; James, 1970). Mulayim (2003) reported a woman with a unicornuate uterus, unilateral ovary, and associated pelvic kidney. Mylonas (2003) reported 3 cases of ovarian agenesis and reviewed the literature, which contained descriptions of another 13 cases. The incidence has been suggested to be approximately 1 in 11,240 women (Sivanesaratnam, 1986).

FALLOPIAN TUBE ANOMALIES

The fallopian tubes develop from the unpaired distal ends of the mÃ¼llerian ducts and extend outward from the superolateral portion of the uterus. The fallopian tubes are between 10 and 14 cm long and normally end by curling around the ovary. A number of congenital and acquired defects of the fallopian tubes have been described by investigators and are discussed below. Disease may be asymptomatic or may be linked to infertility.

Congenital Tubal Disease

Congenital anomalies of the fallopian tube include accessory ostia, complete absence of the fallopian tube, and a number of embryonic cystic remnants (Woodruff, 1969). Remnants of the mesonephric duct in the female include a small structure called the *appendix vesiculosa;* and a few blind tubules in the broad ligaments, the *epoÃ¶phoron;* and a few blind tubules adjacent to the uterus collectively called the *paroÃ¶phoron* (see Fig. 18-2). The epoÃ¶phoron or paroÃ¶phoron may develop into cysts, and those of the epoÃ¶phoron are known as paraovarian cysts. Remnants of the mesonephric duct system are often present in the broad ligaments or are adjacent to the uterus or the vagina as Gartner duct cysts. Remnants of the paramesonephric (mÃ¼llerian) duct in the female may be seen as a small, blind paratubal cysts attached by a pedicle to the distal end of the fallopian tube, the hydatid of Morgagni.

Paratubal cysts are frequent incidental discoveries during gynecologic operations for other abnormalities or are found on sonographic examination (see Fig. 9-16). Most of these cysts are asymptomatic and slow growing and are discovered during the third and fourth decades of life.

In utero exposure to DES has been associated with various tubal abnormalities. Short, tortuous tubes or ones with shriveled fimbria and small ostia have been linked to infertility (DeCherney, 1981).

The congenital versus infectious etiology of salpingitis isthmica nodosa is unresolved. In this disorder, diverticula of the tubal mucosa in the isthmic region extend into the muscularis and to the serosa. It is commonly progressive and leads ultimately to tubal occlusion and infertility (Saracoglu, 1992). Salpingitis isthmica nodosa has also been associated with an increased risk of ectopic

pregnancy.

Acquired Tubal Disease

Acquired fallopian tube disease is due to inflammatory changes of infectious or noninfectious etiology. Infectious causes include pelvic inflammatory disease, tuberculosis or other granulomatous infiltration, ruptured appendix, postoperative infections, or sequela of septic abortion. Of these, pelvic inflammatory disease is the leading cause of tubal disease and is discussed in greater detail in Chapter 3, Pelvic Inflammatory Disease. Noninfectious causes include endometriosis, prior pelvic surgery, or salpingitis isthmica nodosa.

Regardless of the etiology, inflammatory response results in structural alteration and functional impairment of the fallopian tubes. Agglutination or obliteration of the fimbria leads to poor ova retrieval. More proximal obstructions may result from mucus plugs, scarring, and surgical interruption. Such obstructions can disrupt ova transport. In addition, denudation of the tubal epithelium and its cilia results in poor transit of gametes or embryos. Lastly, subfertility can be a consequence of the toxic environment created by intraluminal endometriosis or fluid from a hydrosalpinx.

Approximately one third to one fourth of all infertile women are diagnosed with tubal disease in developed countries (Serafini, 1989; World Health Organization, 2007). Individuals with tubal pathology usually present to the gynecologist or reproductive endocrinologist with complaints of infertility or symptoms of ectopic pregnancy. The HSG has been the traditional test for evaluating tubal status in infertile women, but the primary technique is laparoscopy with chromopertubation (see Figs. 19-5C and 19-8).

Involvement of the female reproductive tract with granulomatous disease is uncommon, but when found tends to involve the fallopian tube. The differential diagnosis of a histologic finding of epithelioid granulomas and giant cells includes tuberculosis (TB), sarcoidosis, brucellosis, leprosy, lymphogranuloma venereum, fungal infections, coccidioidomyocosis, and foreign body reactions (Boakye, 1997).

Tuberculosis continues to be a major cause of morbidity and mortality globally, and is found to be the second leading infectious cause of death among adults worldwide. The precise incidence of genital tuberculosis is difficult to ascertain, as a substantial proportion of cases are asymptomatic and inadvertently uncovered during investigation for infertility. In developing countries, genital TB may account for 3 percent or more of patients with infertility (Aliyu, 2004). In these cases, tubal damage and endometrial adhesions are the underlying cause. For example, the uterine cavity may be completely obliterated by adhesions, resulting in a condition that clinically mimics Asherman syndrome. A disorder in ovum transport further contributes to infertility. The likelihood of a return to fertility after anti-tubercular treatment is low, and in vitro fertilization with embryo transfer remains the most reliable approach to overcoming infertility associated with the disease (Aliyu, 2004).

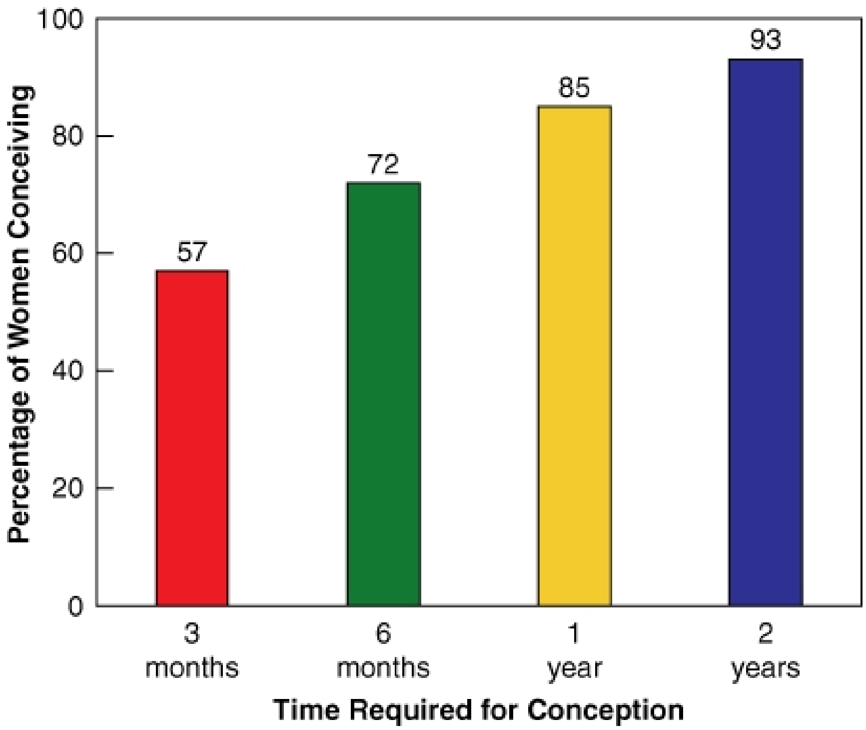
EVALUATION OF THE INFERTILE COUPLE: INTRODUCTION

The inability to conceive after 1 year of unprotected intercourse of reasonable frequency is termed infertility. It can be subdivided into *primary infertility* , that is, no prior pregnancies, and *secondary infertility* , referring to infertility following at least one prior conception. Conversely, *fecundability* is the ability to conceive, and data from large population studies have shown a monthly probability of conceiving of 20 to 25 percent. In those attempting conception, approximately 50 percent of women will be pregnant at 3 months, 75 percent will be pregnant at 6 months, and more than 85 percent will be pregnant by 1 year (Fig. 19-1) (Guttmacher, 1956; Mosher, 1991).

FIGURE 19-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Time required for conception.

Thus, infertility is a common condition, affecting 10 to 15 percent of reproductive-aged couples. Of note, even without treatment, approximately half of women will conceive in the second year of attempting. This information can be reassuring to a couple. Although the prevalence of infertility is believed to have remained relatively stable during the past 40 years, there is no doubt that the demand for infertility evaluation and treatment has increased considerably (Abma, 1997; Hull, 1985; Stephen, 2000; Yao, 2002). The population boom following World War II produced a large group of women now entering the end of their reproductive

life span, many of whom have intentionally delayed pregnancy. Furthermore, with the well-publicized advances in infertility treatment, patients now have greater hope that medical intervention will help them achieve their goal.

Most couples are more correctly considered to be *subfertile,* rather than infertile, as they will ultimately conceive if given enough time. This concept of subfertility can be reassuring to couples. However, there are obvious exceptions, such as the woman with bilaterally obstructed fallopian tubes or the azoospermic male.

It is generally agreed that an infertility evaluation should be considered in any couple that has failed to conceive in 1 year. There are a number of clinical scenarios, however, in which evaluation should be considered sooner. For example, to delay evaluation in an anovulatory woman or a woman with a history of severe pelvic inflammatory disease (PID) may not be appropriate. Furthermore, it is clear that fecundability is highly age related, thus evaluation at 6 months should be performed in any woman older than 40 years, and according to some experts, in woman older than 35.

ETIOLOGY OF INFERTILITY

Successful pregnancy requires a complex sequence of events including ovulation, ovum pick-up by a fallopian tube, fertilization, transport of a fertilized ovum into the uterus, and implantation into a receptive uterine cavity. With male infertility, sperm of adequate number and quality must be deposited at the cervix near the time of ovulation. Remembering these critical events can help direct a clinician to develop an appropriate evaluation and treatment strategy.

In general, infertility can be attributed to the female partner one third of the time, the male partner one third of the time, and both partners in the remaining one third. This approximation emphasizes the importance of evaluating both members of the couple before instituting therapy. Estimates of the incidence of various causes of infertility are shown in Table 19-1 (Abma, 1997; Practice Committee of the American Society for Reproductive Medicine, 2006). Many of these diagnoses are discussed in greater detail in other chapters (Table 19-2).

Table 19-1 Etiology of Infertility	
Male	25%
Ovulatory	27%
Tubal/uterine	22%
Other	9%
Unexplained	17%

Table 19-2 Chapters with Relevant Information About Infertility			
Etiology	**Diagnosis**	**Chapter Title**	**Chapter Number**
Ovulatory dysfunction	PCOS	PCOS and hyperandrogenism	Chapter 17
	Hypothalamic-pituitary	Amenorrhea	Chapter 16
	Age-related	Menopausal Transition	Chapter 21
	POF	Amenorrhea	Chapter 16
Tubal disease	PID	Gynecologic Infection	Chapter 3
Uterine abnormalities	Congenital	Anatomic Disorders	Chapter 18
	Leiomyomas	Pelvic Mass	Chapter 9
	Asherman syndrome	Anatomic Disorders	Chapter 18
Other	Endometriosis	Endometriosis	Chapter 10

PCOS = polycystic ovarian disease; POF = premature ovarian failure; PID = pelvic inflammatory disease.

It should be strongly urged that both partners are present for the initial consultation. A visit to a health care provider for infertility evaluation provides an excellent opportunity for educating a couple regarding the normal process of conception. Many myths surround the ability to conceive, such as the importance of coital position and the need to remain horizontal following ejaculation. These myths can add undue stress to an already stressful situation and should be dispelled.

Couples should be educated regarding the concept of a *fertile window* for conception. The chance of conception is increased from the 5 days preceding ovulation through the day of ovulation (Wilcox, 1995). If the male partner has normal semen characteristics, a couple should have daily intercourse during this period to maximize the chance of conception. Although sperm concentrations will drop with increasing coital frequency, this decrease is not sufficient to negatively impact the chance of fertilization (Stanford, 2002). Couples should also be reminded to avoid oil-based lubricants, which are harmful to sperm.

MEDICAL HISTORY

The Female History

GYNECOLOGIC

As with any medical condition, a thorough history and physical examination is critical (American Society for Reproductive Medicine, 2000). For the female partner, questions should include a complete gynecologic history. Specifically, questions regarding menstruation (frequency, duration, recent change in interval or duration, hot flashes, and dysmenorrhea), prior contraceptive use, coital frequency, and duration of infertility should be asked. Also pertinent is a history of recurrent ovarian cysts, endometriosis, leiomyomas, sexually transmitted diseases, or pelvic inflammatory disease. Because prior conception indicates ovulation and a patent fallopian tube in the patient's past, this history should be sought. A prolonged time to conception may suggest borderline fertility and increase the chance of determining an etiology in a couple. Pregnancy complications such as miscarriage, preterm delivery, retained placenta, chorioamnionitis, or fetal anomalies should be noted. A history of abnormal Pap smears may be pertinent, particularly if a woman underwent cervical conization, which could impact cervical mucus quality and cervical competence (see Section 41-14, Cervical Conization).

When obtaining a medical history, it is critical to discuss coital history, including frequency and timing of intercourse. Symptoms such as dyspareunia may point to endometriosis and a need for earlier laparoscopic evaluation of the female partner.

MEDICAL

The medical history should be aimed at eliciting symptoms of hyperprolactinemia or thyroid disease. Symptoms of androgen excess such as acne or hirsutism may point to the presence of polycystic ovarian syndrome or much less commonly, congenital adrenal hyperplasia. Prior chemotherapy or pelvic irradiation may suggest the presence of ovarian failure.

SURGICAL

The surgical history should focus on pelvic and abdominal surgeries. Surgical treatment of ruptured appendicitis or diverticulitis should raise suspicion for the presence of pelvic adhesive disease or tubal obstruction or both.

MEDICATIONS

Medications should be noted including over-the-counter medications such as nonsteroidal anti-inflammatory drugs, that may adversely affect ovulation. In most instances, use of herbal remedies should be discouraged. Women should be encouraged to take a daily vitamin with at least 400 μg of folic acid to decrease the chance of neural-tube defects.

SOCIAL

A social history should focus on lifestyle and environmental factors such as eating habits and exposure to toxins. Abnormalities in gonadotropin-releasing hormone (GnRH) and gonadotropin secretion are clearly related to body mass indices greater than 25 or less than 17 (Table 1-7). (Grodstein, 1994a). Although difficult to achieve, even modest weight reductions in overweight women have been correlated with normalized menstrual cycles and subsequent pregnancies.

Accumulating data also suggest that cigarette smoking impacts fertility in both women and men (Hughes, 1996; Hull, 2000; Kunzle, 2003; Laurent, 1992; Stillman, 1986). The prevalence of infertility is higher, and the time to conception is longer in women who smoke, or even those exposed passively to cigarette smoke. Toxins in the smoke can accelerate follicular depletion and increase genetic mutations in gametes or early embryos (Sharara, 1994; Shideler, 1989). Admittedly, current data do not prove causation, but only correlation, between smoking and infertility or adverse pregnancy outcomes. Nevertheless, it is estimated that nearly 25 percent of women in the reproductive age group smoke, and the desire for pregnancy can be a powerful motivator toward cessation (Augood, 1998).

Alcohol consumption should also be limited. It is clear that heavy alcohol intake decreases fertility in women and has been associated with a decrease in sperm counts and increase in sexual dysfunction in men (Klonoff-Cohen, 2003; Nagy, 1986). A standardized alcoholic drink is typically defined as 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of hard alcohol. Based on a number of studies, 5 to 8 drinks per week negatively impacts female fertility (Grodstein, 1994b; Tolstrup, 2003). As alcohol is also detrimental to early pregnancy, it is prudent to advise patients to avoid alcohol consumption while trying to conceive.

Caffeine consumption has also been linked to decreased fecundability. A cup of coffee contains approximately 115 mg of caffeine. Most studies suggest that consumption of more than 250 mg of caffeine daily by the female partner is associated with a modest, but statistically significant, decrease in fertility and increase in time to conception. Caffeine intake greater than 500 mg per day has also has been demonstrated to increase recurrent miscarriage rates (Bolumar, 1997; Caan, 1998; Cnattingius, 2000).

Illicit drugs may also impact fecundability. Marijuana suppresses the hypothalamic-pituitary-gonadal axis in both men and women, and cocaine can impair spermatogenesis (Bracken, 1990; Smith, 1987a). Although uncommon, fecundability is reduced with occupational exposure to the dry cleaning fluid perchloroethylene, and to toluene used in the printing business. Heavy metals and pesticides should also be avoided, as they may both decrease fertility rates as well as increase the risk of recurrent miscarriage (Orejuela, 1998).

ETHNICITY

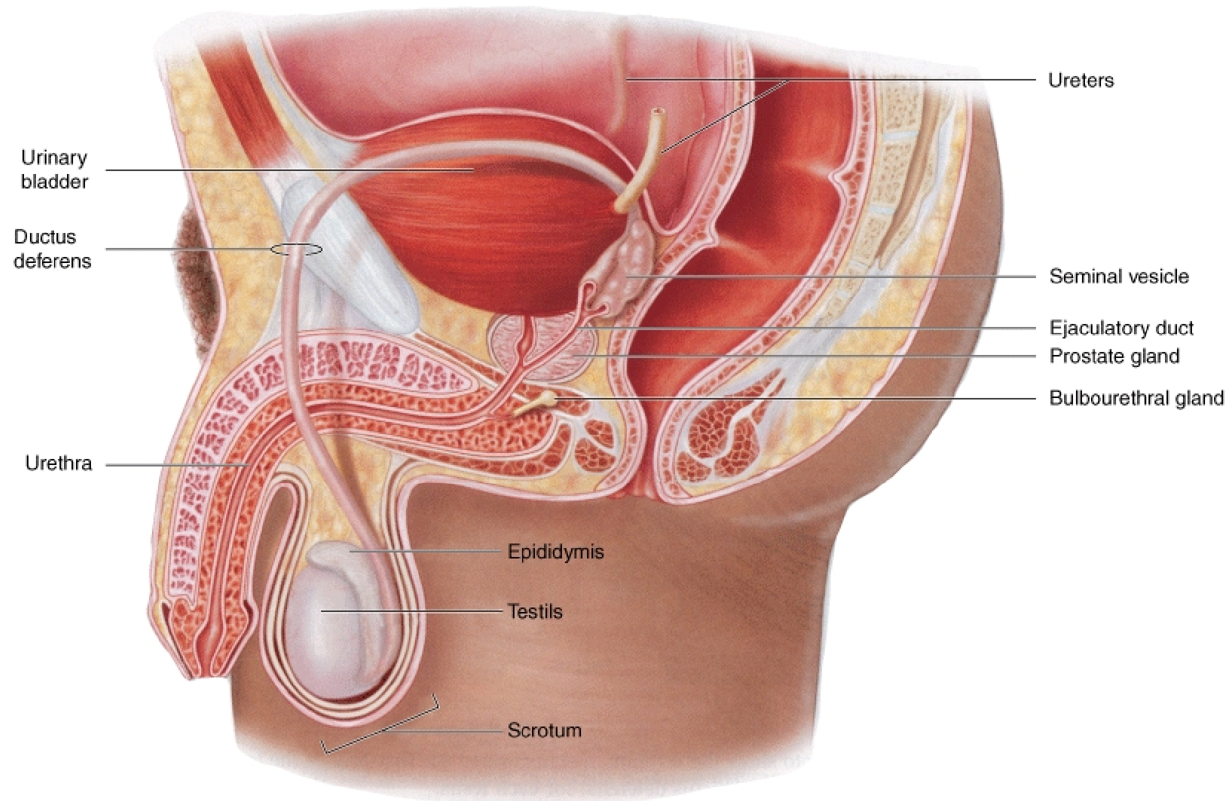
The ethnic background of both partners is important for determining the need for preconceptual testing, such as screening for sickle cell anemia in African-Americans, Tay-Sachs disease and other disorders in Ashkenazi Jews, and cystic fibrosis in patients of northern European descent (American College of Obstetricians and Gynecologists, 2004, 2005; Greenlee, 2003; Hruska, 2000). A family history of infertility, recurrent miscarriage, or fetal anomalies may also point to a genetic etiology. Although the inheritance pattern is complex, data suggest that both polycystic ovarian syndrome and endometriosis occur in familial clusters (see Chaps. 10,

Familial Clustering, and 17, Etiology). For example, it has been estimated that a woman carries a sevenfold increased risk of endometriosis over the general population if a single first-degree family member has the disease (Moen, 1993).

The Male History

The process of spermatogenesis, from stem cell to mature sperm, takes nearly 90 days, and therefore any detrimental event in the prior 3 months can adversely affect semen characteristics (Hinrichsen, 1980; Rowley, 1970). Spermatogenesis is optimal at temperatures slightly below body temperature, thus the location of the testes outside of the pelvis (Fig. 19-2). Illness with high fevers or chronic hot tub use can temporarily impair sperm quality. There is no definitive evidence that boxer underwear is advantageous (Tas, 1996).

FIGURE 19-2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Male genitalia. *(From McKinley, 2006, with permission.)*

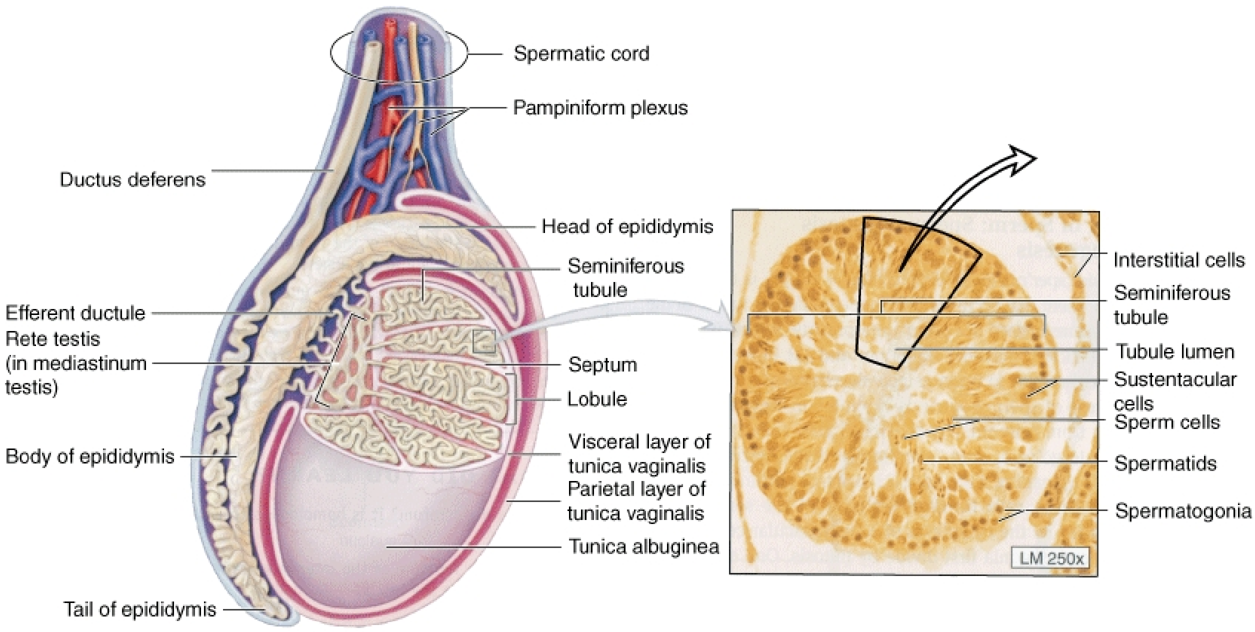
The male partner should be questioned regarding pubertal development and difficulties with sexual function. Erectile dysfunction, particularly in conjunction with decreased beard growth, may suggest decreased testosterone levels. Ejaculatory dysfunction should also be evaluated, including the presence of developmental anomalies such as hypospadias, which could result in suboptimal semen deposition (Benson, 1997).

Sexually transmitted diseases or frequent genitourinary infections, including epididymitis or prostatitis, may result in obstruction of the vas deferens. Mumps in an adult can result in testicular inflammation and damage to the spermatogenic stem cells (Beard, 1977). A history of cryptorchidism, testicular torsion, or testicular trauma may suggest the presence of abnormal spermatogenesis (Anderson, 1990; Bartsch, 1980; Sigman, 1997; Tas, 1996). Compared with fertile males, males with a history of unilateral or bilateral cryptorchidism have fertility rates of 80 percent and 50 percent, respectively (Lee, 1993). The reason for poor semen

characteristics in these patients is unclear. The relatively warm intra-abdominal temperature may cause permanent damage to the stem cells. Alternatively, genetic abnormalities that led to the abnormal location of the testes may also affect sperm production.

A history of varicocele should also be obtained. A varicocele consists of dilated veins of the pampiniform plexus of the spermatic cords that drain the testes (Figs. 19-3A). Varicoceles are believed to raise scrotal temperature, however, controversy exists regarding the impact of varicoceles on fertility (Chehval, 1992; Jarow, 2001; World Health Organization, 1992). Although 30 to 40 percent of men seen in infertility clinics are diagnosed with a varicocele, nearly 20 percent of men in the general population are similarly affected. There is also substantial disagreement on the benefits gained from varicocele repair, particularly for subclinical varicoceles, which are only detectable by sonography (Kim, 1999; Schlesinger, 1994; Steckel, 1993). Nevertheless, if a varicocele is suspected, it should be evaluated by a urologist, preferably one with a specific interest in infertility.

FIGURE 19-3



A Testis

B Seminiferous tubule

(1) Germ cells that are the origin of sperm cells are *diploid* (2n=46) cells called spermatogonia. Mitotic divisions of these cells produce a new germ cell and a committed cell. The committed cell is a primary spermatocyte.

(2) The first meiotic division begins in the *diploid* primary spermatocytes. The *haploid* (n=23) cells produced by the first division are called secondary spermatocytes.

(3) The second meiotic division originates with the secondary spermatocytes and produces spermatids.

(4) The process of spermiogenesis results in morphological changes needed to form sperm cells that will be motile.

C Spermatogenesis

The medical history should focus on prior treatment with chemotherapy or local radiation therapy that may damage the spermatogonial stem cells. Hypertension, diabetes mellitus, and neurologic disorders may be associated with erectile dysfunction or retrograde ejaculation. A number of medications are known to adversely impact semen parameters including cimetidine, erythromycin, gentamicin, tetracycline, and spironolactone (Sigman, 1997). As described above, cigarettes, alcohol, illicit drugs, and environmental toxins all adversely affect semen parameters (Muthusami, 2005; Ramlau-Hansen, 2007). The increasing use of anabolic steroids also decreases sperm production by suppressing the production of intra-testicular testosterone (Gazvani, 1997). Although the effects of many medications are reversible, anabolic steroid abuse may lead to lasting or even permanent damage to testicular function.

PHYSICAL EXAMINATION

Examination of the Female Patient

A physical examination may provide many clues to the cause of infertility. Vital signs, height, and weight should be recorded. Hirsutism, alopecia, or acne indicates the need to measure androgen levels. The presence of acanthosis nigricans is consistent with insulin resistance associated with polycystic ovarian syndrome or much less commonly, Cushing syndrome. Additionally, thyroid abnormalities should be noted. The evaluation and treatment of endocrine abnormalities that impact reproductive function are described in greater detail in Chapters 16, Evaluation and 17, Metabolic Syndrome and Cardiovascular Disease.

A pelvic exam may be particularly informative. Inability to place a speculum through the introitus may raise doubts about coital frequency. The vagina should be moist and rugated, and the cervix should have a reasonable amount of mucus, both indicating adequate estrogen production. An enlarged or irregularly shaped uterus may reflect leiomyomas, whereas a fixed uterus suggests the presence of pelvic scarring due to endometriosis or prior pelvic infection. Uterosacral nodularity or ovarian masses may additionally implicate endometriosis.

All women should have a normal Pap smear result within the year preceding treatment. Negative cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should be obtained to ensure that cervical manipulation during evaluation and treatment does not cause an ascending infection. The breast examination must be normal, and when indicated by age or family history, a mammogram should be obtained prior to initiating hormonal treatment.

Examination of the Male Patient

Most gynecologists will not feel comfortable performing a complete physical examination of the male. Nevertheless, parts of this evaluation are relatively easy to perform, and a gynecologist at minimum should understand the primary focus of the examination. As signs of testosterone production, normal secondary sexual characteristics such as beard growth, axillary and pubic hair, and perhaps male pattern balding should be present. Gynecomastia or eunuchoid habitus may suggest Klinefelter syndrome (47,XXY karyotype) (De Braekeleer, 1991).

The penile urethra should be at the tip of the glans for proper semen deposition in the vagina. Testicular length should be at least 4 cm with a minimal testicular volume of 20 mL (Charny, 1960; Hadziselimovic, 2006). Small testes are unlikely to be producing normal sperm numbers. The presence of a testicular mass may indicate the presence of testicular cancer, which can present as infertility. The epididymis should be soft and nontender to exclude chronic infection (see Fig. 19-2). Epididymal fullness can suggest obstruction of the vas deferens. The prostate should be smooth, nontender, and normal size. Additionally, the pampiniform plexus of veins should be palpated for varicocele (Jarow, 2001). Importantly, both vas deferens should be palpable. Congenital bilateral absence of the vas deferens is associated with mutation in the gene responsible for cystic fibrosis (Anguiano, 1992).

EVALUATION FOR SPECIFIC CAUSES OF INFERTILITY

The infertility evaluation can be conceptually simplified into confirmation of: (1) ovulation, (2) normal female reproductive tract anatomy, and (3) normal semen characteristics. The specifics regarding evaluation of each of these categories will be detailed in the following sections and is shown in Table 19-3.

Table 19-3 Infertility Testing

Etiology	Evaluation
Ovulatory dysfunction	Serum midluteal progesterone Ovulation predictor kit Early follicular FSH Â± estradiol level (ovarian reserve) Â± Serum measurements (TSH, prolactin, androgens) Â± Ovarian sonography (antral follicle count) Â± Basal body temperature chart Â± Endometrial biopsy (luteal phase defect)
Tubal/pelvic disease	Hysterosalpingography Laparoscopy with chromotubation
Uterine factors	Hysterosalpingography Transvaginal sonography Saline-infusion sonography Magnetic resonance imaging Hysteroscopy Laparoscopy
Cervical factor	Â± Postcoital test
Male factor	Semen analysis

FSH = follicle-stimulating hormone; TSH = thyroid-stimulating hormone.

Etiology of Infertility in the Female

OVULATORY DYSFUNCTION

Ovulation may be perturbed by abnormalities within the hypothalamus, anterior pituitary, or ovaries. Hypothalamic disorders may be due to lifestyle, for example, excessive exercise, eating disorders, or stress. Alternatively, dysfunction or improper migration of the hypothalamic gonadotropin-releasing hormone neurons may be inherited, such as that which occurs in idiopathic hypothalamic hypogonadism (IHH) or Kallman syndrome (see Chap. 16, Hypogonadotropic Hypogonadism). Thyroid disease and hyperprolactinemia may also contribute to menstrual disturbances. A full discussion of disorders that result in menstrual disturbances are discussed in Chapter 16.

Menstrual Pattern

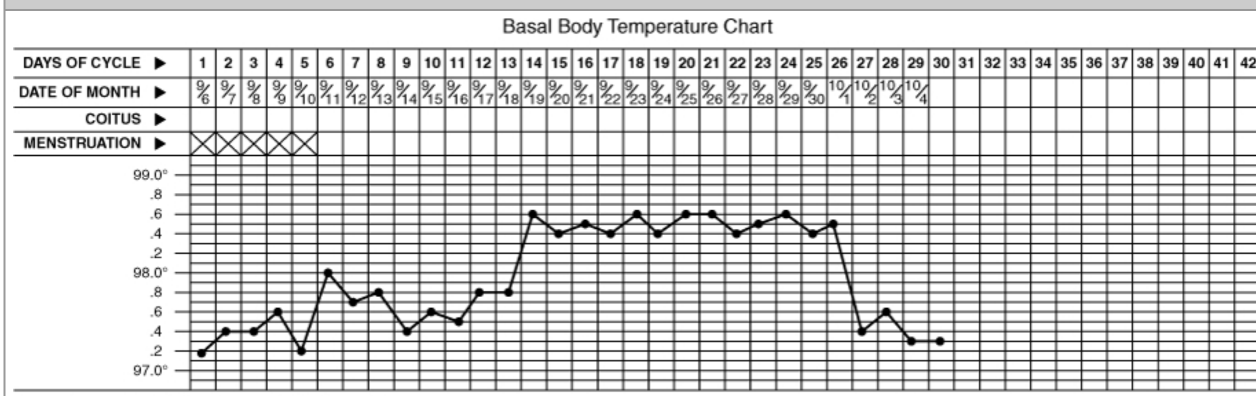
A patient's menstrual history is an excellent predictor of regular ovulation. A woman with cyclic menses at an interval of 25 to 35 days and duration of bleeding of 3 to 7 days is most likely ovulating. Although there is a wide variation in these numbers, each woman will have her own normal pattern. Therefore, these figures should not significantly vary across cycles for an individual woman.

Probable ovulation is also suggested by the presence of *mittelschmerz,* which is midcycle pelvic pain associated with ovulation, or moliminal symptoms such as breast tenderness, acne, food cravings, and mood changes. Ovulatory cycles are more likely to be associated with dysmenorrhea, although severe dysmenorrhea may suggest the presence of endometriosis.

Basal Body Temperature

Basal body temperature (BBT) charting has long been used to identify ovulation. This test requires that a woman's morning oral temperature be graphically charted. Oral temperatures are usually 97.0Â° to 98.0Â°F during the follicular phase. A postovulatory rise in progesterone levels increases basal temperature by approximately 0.4Â° to 0.8Â°F. This *biphasic* temperature pattern is strongly predictive of ovulation (Bates, 1990). Nevertheless, although this test has the advantage of being inexpensive, it is insensitive in many women. Furthermore, for a couple wishing to conceive, the temperature increase follows ovulation, and therefore the window of maximal fertility has been missed (Grinsted, 1989; Luciano, 1990; Moghissi, 1992). Although this test may be useful for a couple first attempting to conceive, it has generally fallen out of favor as an infertility diagnostic tool (Fig. 19-4).

FIGURE 19-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Biphasic pattern seen on this basal body temperature chart suggests ovulation. *(From Chang, 2005, with permission).*

Ovulation Predictor Kits

A number of additional tests for ovulation have been developed. Urinary ovulation predictor kits are widely available in pharmacies.

These kits, which measure the concentration of urinary luteinizing hormone (LH) by colorimetric assay, have become relatively easy to use and provide clear instructions regarding interpretation.

In general, a woman should begin testing 2 to 3 days prior to the predicted LH surge, and testing should be continued daily. There is no clear consensus regarding the optimal time of day to test. Some infertility specialists suggest that the concentrated first morning void is a logical testing time, whereas others are concerned that this sample may demonstrate a false-positive or equivocal result. Other clinicians reason that the serum LH peak occurs in the morning and that the greatest likelihood of detecting a urinary peak would be in the late afternoon or evening. Timing is probably not critical as long as the test is performed daily, as the LH surge spans only 48 to 50 hours. In most instances, ovulation will occur the day following the urinary LH peak (Luciano, 1990; Miller, 1996).

If equivocal results are obtained, the test can be repeated in 12 hours. In one study, urine LH surge assays were estimated to have 100-percent sensitivity and 96-percent accuracy, although this is undoubtedly an overestimate of typical-use results (Grinsted, 1989; Guermandi, 2001).

Serum Progesterone

Ovulation can also be tested by measuring midluteal phase serum progesterone levels. In a classic 28-day cycle, serum is obtained on cycle day number 21 following the first day of menstrual bleeding, or 7 days following ovulation. Levels during the follicular phase are generally <2 ng/mL. Values above 4 to 6 ng/mL are highly correlated with ovulation and subsequent progesterone production by the corpus luteum (Guermandi, 2001). Progesterone is secreted as pulses, and therefore a single measurement is not indicative of overall production during the luteal phase. As a result, an absolute threshold for acceptable progesterone levels has not been clearly established. Nevertheless, Hull and colleagues (1982) have reported that a midluteal progesterone concentration of greater than 9.4 ng/mL is predictive of higher pregnancy rates than those observed in patients with progesterone levels less than 10 ng/mL.

Many clinicians choose to empirically treat any patient with a progesterone level below this value with natural progesterone. Although this approach is unlikely to be harmful, the utility of this management is unproven. Accordingly, the midluteal progesterone level is best regarded as an excellent measure for the occurrence of ovulation, but not an absolute indicator of adequate luteal function.

Endometrial Biopsy

Adequate progesterone levels are required for endometrial preparation prior to implantation. Inadequate progesterone levels are believed to result in luteal phase defect (LPD). Thus, it was proposed that an endometrial biopsy would represent both the function of a corpus luteum as well as the endometrial response, thereby providing more clinically relevant information than a serum progesterone level alone. Noyes and associates (1975) described a sequence of histologic events in the endometrium in the periovulatory, luteal, and early menstrual stages. These investigators defined LPD as a lag in the histologic appearance of the endometrium of greater than 2 days relative to the actual day of the cycle. This discrepancy in dating is termed an *out-of-phase biopsy* . Classically, an endometrial biopsy is obtained as close to the impending menstrual cycle as possible based on previous cycle length, and more recently, on the timing of the LH surge.

Unfortunately, the utility of this test is severely hampered by high intra-observer and inter-observer variability (Balasch, 1992; Scott, 1993). The estimated frequency of LPD in the infertile population has ranged widely, but is generally agreed to be between 5 and 10 percent. Nevertheless, it appears that a finding of an out-of-phase biopsy occurs nearly as frequently in fertile as in infertile women, with a large overlap in incidence between the two groups (Aksel, 1980; Balasch, 1992; Davis, 1989; Scott, 1993). This observation has led many experts to conclude that LPD may not exist as a clinical entity. Certainly in its current form, the endometrial biopsy has little predictive value. For all of these reasons, this test is no longer considered a routine part of the infertility evaluation.

It is interesting to note that impressive advances are being made in our understanding of the timing of protein expression in the endometrial glands and stroma. Potential markers for uterine receptivity include osteopontin, cytokines (leukemia inhibitory factor, colony-stimulating factor-1, and interleukin-1), cell adhesion molecules (the integrins), and the L-selectin ligand, which has been

proposed to mediate embryo attachment (Carson, 2002; Kao, 2003; Lessey, 1998). In the future, endometrial biopsies may again become part of the diagnostic evaluation if expression patterns of these proteins prove to be predictive of endometrial receptivity.

Sonography

Serial ovarian sonography can demonstrate the development of a mature antral follicle and its subsequent collapse during ovulation. This approach is rather time consuming and ovulation can be missed. However, sonography is an excellent approach for supporting the diagnosis of polycystic ovarian syndrome with its associated oligo-anovulation Fig. 17-11).

FEMALE AGING AND OVULATORY DYSFUNCTION

Epidemiology

There is a clear inverse relationship between female age and fertility (Table 19-4). A classic study was performed in the Hutterites, a community that eschews contraception. After ages 34, 40, and 45, the incidence of infertility was 11 percent, 33 percent, and 87 percent, respectively. The average age at last pregnancy was 40.9 years (Tietze, 1957). Another interesting study evaluated cumulative pregnancy rates in women using donor insemination. In women less than 31 years old, 74 percent achieved pregnancy within 1 year. These rates fell to 62 percent for women between 31 and 35 years, and further declined to 54 percent in women older than 35 (Treloar, 1998).

Table 19-4 Female Aging and Infertility

Female Age (years)	Infertility
20â€"29	8.0%
30â€"34	14.6%
35â€"39	21.9%
40â€"44	28.7%

Physiology

Age-related infertility is most closely linked to the loss of viable oocytes. At midgestation, a normal human female fetus has approximately seven million oocytes, which will decrease to between two and three million by birth (see Fig. 14-1). Ongoing atresia of nondominant follicles proceeds throughout a woman's reproductive life span, with approximately 300,000 follicles at puberty and <1,000 follicles at the onset of menopause. Thus, even before a female reaches menarche, she has lost most of her eggs. A fuller discussion of pubertal and menopausal physiology can be found in Chapters 14 and 21.

As a woman ages, there is a substantially increased risk of genetic abnormalities as well as mitochondrial deletions in the remaining oocytes (Keefe, 1995; Pellestor, 2003). These factors result in decreased pregnancy rates and increased miscarriage rates in both spontaneous and treatment cycles. The overall miscarriage risk in women older than 40 years has been estimated to be 50 to 75 percent (Maroulis, 1991).

The rate of follicular loss and age at menopause varies between women and is likely genetically determined. For example, a family history of early menopause is correlated with an increased risk of early menopause in an individual woman. In general, the age at last birth in naturally fertile populations averages 10 years prior to the menopause (Nikolaou, 2003; te Velde, 2002). However, in most cases, it is impossible to predict the onset of menopause, and therefore testing is indicated to determine current fertility potential in older women.

Follicle-Stimulating Hormone Levels

Measurement of serum follicle-stimulating hormone (FSH) levels in the early follicular phase is a simple and sensitive predictor of ovarian reserve (Toner, 1991). With declining ovarian function, the support cells (granulosa cells and luteal cells) secrete less inhibin, a peptide hormone which is responsible for inhibiting FSH secretion by the anterior pituitary gonadotropes (see Chap. 15,

Gonadotropins and Follicular Development). With loss of luteal inhibin, FSH levels rise in the early follicular phase. Measurement of serum FSH levels is classically completed on cycle day number 3 following the onset of menses. A value greater than 10 mIU/mL indicates significant loss of ovarian reserve and should prompt a more rapid evaluation and more intensive treatment. In a large study evaluating in vitro fertilization cycles, a day-3 FSH level exceeding 15 mIU/mL was predictive of significantly lower pregnancy rates (Muasher, 1988; Scott, 1995; Toner, 1991).

Estradiol Levels

Many clinicians also measure serum estradiol levels simultaneously (Buyalos, 1997; Licciardi, 1995). Addition of an estradiol measurement may decrease the incidence of false-negative results of FSH values alone. Somewhat paradoxically, despite the overall depletion of ovarian follicles, estrogen levels in older women will be elevated early in the cycle due to increased stimulation of ovarian steroidogenesis by elevated FSH levels. A cycle-day-3 estradiol level of >80 pg/mL is considered abnormal. It should be noted that reference levels for estradiol and FSH can vary between laboratories. Therefore, every clinician should become familiar with their own laboratory's normal values.

Clomiphene Citrate Challenge Test

The clomiphene citrate challenge test (CCCT) is believed to be a more sensitive indicator of diminished ovarian reserve than measurement of "unstimulated" hormone levels (Navot, 1987). Clomiphene citrate is a nonsteroidal estrogen receptor modulator. Although the exact mechanism is not fully understood, clomiphene is believed to block the negative feedback inhibition of endogenous estrogens on FSH secretion. (see Fig. 20-1). With the test, a woman takes 100 mg of clomiphene citrate orally on cycle day numbers 5 through 9. Estradiol and FSH levels are measured on day 3, and an FSH level is measured on day 10. Follicle-stimulating hormone elevations at either time point are indicative of diminished ovarian reserve.

In general, a simple day-3 FSH level measurement is probably adequate as an initial screen. However, consideration should be given to performing a CCCT in any woman with a borderline FSH level or who is older than 40 years. Moreover, an FSH or CCCT should be strongly considered in any woman with a history of ovarian surgery, chemotherapy, or irradiation. Testing may also be done in those with a smoking history, poor response to gonadotropins, age greater than 35 years, or a family history of early menopause.

Sonography

Additional methods of evaluating ovarian reserve are under study. One of the best validated is the use of transvaginal sonography to measure ovarian volume and obtain an early follicular phase antral follicle count (Frattarelli, 2000). The number of small antral follicles reflects the size of the resting follicular pool. Less than 10 antral follicles predicts poor response to gonadotropin stimulation.

Testing Interpretation

Abnormal testing through any of the above methods correlates consistently with a poor prognosis for achieving pregnancy whatever the woman's age. Conversely, a normal test does not negate the impact of a woman's age on her fertility status. This information may be useful in counseling a couple about prognosis. Poor results in an older woman can supply an impetus to either attempt donor oocyte in vitro fertilization (IVF), or pursue alternatives such as adoption. Borderline results in a younger woman may suggest a need for a more intensive approach.

TUBAL AND PELVIC FACTORS

Symptoms such as chronic pelvic pain or dysmenorrhea may suggest the presence of tubal obstruction or pelvic adhesions or both. Adhesions can prevent normal tubal movement, ovum pick-up, and transport of the fertilized egg into the uterus. A wide variety of etiologies may contribute to tubal disease, including pelvic infection, endometriosis, and prior pelvic surgery.

A history of pelvic inflammatory disease (PID) is highly suspicious for damage to the fallopian tubes or the presence of pelvic adhesions. In the United States, the most common causes of tubal disease are infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae,* whereas tuberculosis is a common cause of both tubal and intrauterine disease in countries with endemic infection and should be considered in immigrant populations. Tubal infertility has been estimated to follow in 12 percent, 23 percent, and 54

percent of women following one, two, or three cases of PID, respectively (Lalos, 1988). Nevertheless, a lack of PID history is not overly reassuring, as nearly one half of patients who are found to have tubal damage have no history of antecedent disease (Rosenfel, 1983).

Inflammation and chronic bleeding within implants of endometriosis can also lead to obstruction of fallopian tubes or development of severe pelvic adhesions. In addition, a history of ectopic pregnancy, even if treated medically with methotrexate, implies the likelihood of significant tubal damage. Residual adhesions are common after even the most meticulous pelvic surgery, particularly in cases of pelvic inflammation, due to the presence of blood, infection, or the irritation caused by the contents of mature cystic teratomas (dermoids).

Testing for tubal patency can be performed by hysterosalpingography (HSG) or by chromotubation during laparoscopy. Chapter 2, Hysterosalpingography contain additional discussion of HSG performance. Fimbrioplasty may be considered in cases of distal tubal obstruction without significant hydrosalpinx. Attempts may also be made to correct proximal obstruction with balloon tuboplasty via hysteroscopy. However, with the advent of successful pregnancy rates using IVF, tubal surgery rates are decreasing.

UTERINE ABNORMALITIES

Congenital Anomalies

Uterine anomalies can be either inherited or acquired. As described in Chapter 18, Incidence and Classification, inherited anomalies include uterine septum, bicornuate uterus, unicornuate uterus, and uterine didelphys. With the possible exception of a large uterine septum, the impact of these anomalies on conception has been difficult to verify, although a subset are clearly associated with pregnancy complications. As a uterine septum can now be removed relatively simply and safely with hysteroscopy, most infertility specialists will proceed with surgery if this anomaly is identified.

Diethylstibesterol

In utero exposure to this synthetic estrogen has been linked to malformations of uterine development in addition to an increased risk for vaginal adenosis. More information on this topic can be found in Chapter 18, Acquired Uterine Defects. The classic uterine appearance is a small, T-shaped uterus. This cohort of women is seen progressively less frequently in infertility clinics as they pass reproductive age (Goldberg, 1999).

Acquired Abnormalities

Acquired anomalies include intrauterine polyps, leiomyomas, and Asherman syndrome.

Endometrial Polyps

These soft fleshy growths are estimated to be present in 3 to 5 percent of infertile women (Farhi, 1995; Soares, 2000). The prevalence is higher in women with symptoms, such as intermenstrual or postcoital bleeding. Although these complaints typically prompt hysteroscopic removal, most data have not clearly demonstrated an indication for removing polyps in otherwise asymptomatic women (Ben-Arie, 2004; DeWaay, 2002). Of note, however, a recent study has suggested that removal of even small polyps (under 1 cm) may improve pregnancy rates following intrauterine insemination (Perez-Medina, 2005).

Leiomyomas

These benign smooth muscle tumors may also prevent normal implantation, depending on their size and location (Pritts, 2001). Certainly, it seems reasonable to assume that leiomyomas that obstruct a fallopian tube, distort the uterine cavity (submucosal leiomyomas), or fill the uterine cavity (intracavitary leiomyomas) would be detrimental to implantation. The endometrium overlying these tumors is less vascular and the surrounding myometrium exhibits dysfunctional contractility, both of which may contribute to decreased rates of successful pregnancy. It seems equally reasonable to postulate that a subserosal leiomyoma would not impact pregnancy. Additional discussion on this topic can be found in Chapter 9, Infertility and Pregnancy Wastage.

Farhi and colleagues (1995) studied the effects of uterine leiomyomas on IVF success rates. In 28 women with a normal uterine cavity, the pregnancy rate was 30 percent per embryo transfer. In 18 women with an abnormal cavity, the pregnancy rate was only 9 percent per transfer. Although this suggests that removal of submucous leiomyomas should improve fecundability, there are no randomized, prospective trials to confirm this conclusion.

Appropriate intervention is even more ambiguous in the patient with intramural leiomyomas that do not abut the endometrium (Stovall, 1998). Thus far, it has not been possible to develop an algorithm based on number, volume, or location of these tumors that accurately predicts the need to remove them, either to improve implantation rates or decrease pregnancy complications such as miscarriage, placental abruption, or preterm labor. Nevertheless, most experts will consider surgical removal of a leiomyoma greater than 5 cm or multiple smaller tumors in this size range. Surgical complications are discussed in atlas Section 41-18, Myomectomy. These include creation of Asherman syndrome following the removal of large submucosal leiomyomas or the need for cesarean delivery if the full myometrial thickness is transected.

Asherman Syndrome

The presence of intrauterine adhesions, also called *synechiae* , is termed *Asherman syndrome* . This diagnosis is discussed in detail in Chapter 18, Asherman Syndrome. Asherman syndrome occurs most frequently in women with a history of uterine dilation and curettage, particularly in the context of infection and pregnancy (Schenker, 1996). A woman with an intrauterine device (IUD) complicated by infection is also at high risk for the development of intrauterine adhesions. The clinical history will often include an acute postsurgical decrease in menstrual bleeding or even amenorrhea. Treatment of Asherman syndrome involves hysteroscopic lysis of the adhesions as described in atlas Section 41-41, Lysis of Intrauterine Adhesions. Although dilation and curettage has been used, hysteroscopy provides more precise control with less secondary scarring. Electrosurgical coagulation is rarely required, as the bands are in most cases composed of dense connective tissue with poor blood supply.

RADIOLOGIC AND SURGICAL APPROACHES FOR EVALUATION OF PELVIC STRUCTURES

There are five major approaches for evaluating pelvic anatomy: (1) hysterosalpingography, (2) transvaginal sonography with or without saline instillation, (3) hysteroscopy, (4) laparoscopy, and (5) pelvic imaging by magnetic resonance (MR) imaging. As shown in Table 19-5, each has its own advantages and disadvantages.

Table 19-5 Advantages and Disadvantages of Various Methods for Evaluating Pelvic Anatomy

	Tubal Patency	Uterine Cavity	Developmental Defects	Endometriosis or PAD	Ovaries
HSG	+	+	â€“	+/â€“	â€“
SIS	â€“	+	+/â€“	â€“	+
MR imaging	â€“	+	+	â€“	+
Hysteroscopy	â€“	+	+ (with laparoscopy)	â€“	â€“
Laparoscopy	+	â€“	+ (with hysteroscopy)	+	+

HSG = hysterosalpingography; MR = magnetic resonance; PAD = pelvic adhesive disease; SIS = saline-infusion sonography.

Hysterosalpingography

This radiographic tool can be useful for evaluating the shape and size of the uterine cavity, in addition to defining tubal status (see Chap. 2, Hysterosalpingography). Hysterosalpingography is generally performed on cycle day numbers 5 through 10. At this time, there should be minimal intrauterine clotting that could block tubal outflow or give the false impression of an intrauterine abnormality. Furthermore, a woman should not have ovulated and possibly conceived. For this test, iodinated contrast medium is infused through a catheter placed into the uterus. Under fluoroscopy, dye is followed as it fills the uterine cavity, then the tubal lumen, and finally spills out of the tubal fimbriae into the pelvic cavity (Fig. 19-5).

Hysterosalpingogram findings. These images are digitally reversed, causing the radiopaque contrast to appear black against a radiolucent background. **A.** Normal hysterosalpingogram. Radiopaque dye fills the uterine cavity and spills from both fallopian tubes into the peritoneal cavity. The dye catheter is seen beneath the endometrial contour. **B.** Asherman syndrome. Contrast dye fills a small and irregularly shaped endometrial cavity, often described as having a "moth-eaten" appearance. **C.** Bilateral hydrosalpinges. Note the marked tubal dilation and lack of spill of contrast medium at the fimbrial ends. *(Courtesy of Drs. Kevin Doody and Bala Bhagavath.)*

Tubal Disease

In a large meta-analysis, HSG was demonstrated to have 65-percent sensitivity and 83-percent specificity for tubal obstruction (Swart, 1995). Tubal contractions, particularly cornual spasm, can give the incorrect impression of proximal fallopian tube obstruction (a false-positive result). Much less commonly reported is a scenario in which a false-negative result is obtained when the fallopian tube is seen as patent by HSG, although subsequently it is determined to be blocked. Many causes of tubal disease affect both tubes, and therefore it is clinically unusual to have unilateral disease. Unilateral obstruction with a normal contralateral tube is most likely due to the dye following the path of least resistance during the HSG procedure, however, laparoscopy with chromotubation should be considered prior to treatment to confirm a final diagnosis.

Hysterosalpingography is not reliable in detecting peritubal or pelvic adhesions, although loculation of dye around the tubes may be suggestive (see Fig. 19-5). Thus, HSG is an excellent predictor of tubal patency, but is less effective at predicting normal tubal function or the presence of pelvic adhesions. Pregnancy rates have been reported to be increased following HSG, and have been suggested to result from flushing of intratubal debris. However, these reports followed evaluation with oil-based dyes rather than water-based dyes, which are currently preferred.

Uterine Pathology

Hysterosalpingography also provides analysis of the contour of the intrauterine cavity. A polyp, leiomyoma, or adhesion within the cavity will block dye diffusion, resulting in an intrauterine "defect" in dye opacity on radiograph (Fig. 19-6). False-positives may be obtained due to the presence of blood clots, mucus plugs, or shearing of the endometrium during placement of the intrauterine catheter.

FIGURE 19-6

Appearance of leiomyoma and endometrial polyps on hysterosalpingogram (HSG). **A.** A broad-based filling defect is formed during HSG by a submucous leiomyoma. Note distortion of the left cornu by this mass. **B.** A more irregular filling defect is created by an endometrial polyp. Note that polyps generally have a less substantial attachment to the myometrium. *(Courtesy of Dr. Diane Twickler.)*

Hysterosalpingography can also define developmental uterine anomalies (Fig. 19-7). In general, developmental uterine anomalies are not causative for infertility, but may be associated with miscarriage or later fetal loss, creating a management dilemma. It may

be reasonable to surgically treat a uterine anomaly in an effort to improve pregnancy outcome. However, a couple must be carefully counseled that fertility itself is unlikely to be affected. A further discussion of the fertility effects of congenital anomalies is found in Chapter 18, Incidence and Classification.

Hysterosalpingogram appearance of mÃ¼llerian developmental anomalies. **A.** Bicornuate uterus, due to a failure of fusion of the mÃ¼llerian ducts, produces a fundal defect with wide-spaced uterine horns. **B.** Septate uterus due to a failure of resorption. This moderate septum displaces the radiopaque dye to the level of the radiolucent injector balloon. C. Uterine didelphys consisting of two completely separate mÃ¼llerian systems including duplication of the cervix. *(Courtesy of Dr. Diane Twickler.)*

A Y-shaped uterus on hysterosalpingography may represent either a uterine septum or bicornuate uterus. In these cases, the external contour of the uterine fundus must be evaluated using MR imaging, high resolution sonography, or laparoscopy (see Fig. 2-27). A smooth fundal contour is consistent with a diagnosis of uterine septum. This is an important distinction, as a septum is often resected, but a bicornuate uterus is generally not treated.

Hysterosalpingography has been shown to accurately identify intrauterine pathology. In one study of over 300 women in which hysteroscopy was used as the gold standard, HSG was determined to be 98-percent sensitive and 35-percent specific, with a positive predictive value of 70 percent and a negative predictive value of 8 percent. Most misdiagnoses were due to an inability to distinguish polyps from submucous leiomyomas, a minimal problem, as these patients will undergo further evaluation and treatment in either case (Preutthipan, 2003; Randolph, 1986). Although other studies have not provided such impressive results, it is clear that HSG is a powerful tool for evaluation of the uterine cavity.

Sonography

Transvaginal pelvic sonography may also be helpful in determining uterine anatomy, particularly during the luteal phase, when the thickened endometrium acts as contrast to the myometrium. Although not yet widely available, the development of three-dimensional ultrasound machines is advancing the discriminatory abilities of sonography.

The infusion of saline into the endometrial cavity during follicular phase sonography provides another approach for achieving contrast between the cavity and uterine walls. This procedure has many names including saline ultrasound, hysterosonography, sonohysterography, or saline-infusion sonography (SIS). Details of this procedure are described in Chapter 2, Saline-Infusion Sonography. Saline-infusion sonography has been reported to have a sensitivity of 75 percent and specificity of over 90 percent. It has an acceptable positive predictive value of 50 percent and an excellent negative predictive value of 95 percent, which greatly exceeds the negative predictive value of HSG (Soares, 2000). Moreover, SIS may be more sensitive than HSG in determining whether a cavitary defect is a pedunculated leiomyoma or a polyp (Figs. 8-7 and 8-8). Perhaps more importantly, SIS can help determine what portion of a submucous leiomyoma is within the cavity, as only those with less than a 50-percent intramural component should be approached by hysteroscopy.

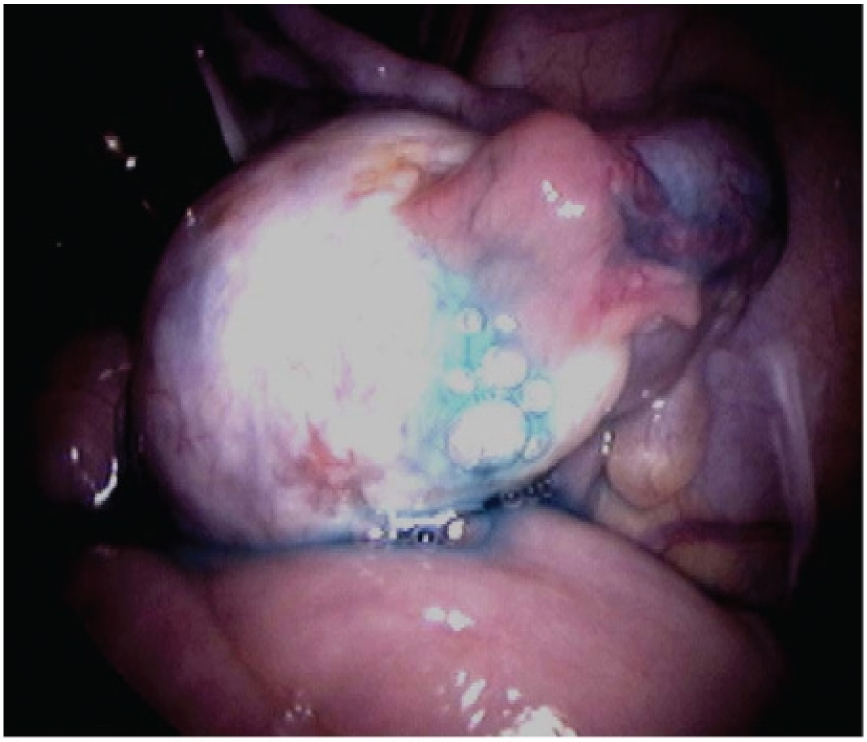
The primary limitation of SIS is that it does not provide information about the fallopian tubes, although rapid loss of saline into the pelvis is certainly consistent with at least unilateral patency. Saline-infusion sonography is generally less painful than HSG and

does not require radiation exposure. Therefore, it is the preferred method if information about tubal patency is not required, such as in patients who are known to require in vitro fertilization.

Laparoscopy

Direct inspection provides the most accurate assessment of pelvic pathology and laparoscopy is the gold standard approach. Chromotubation may be performed, and a dilute dye is injected through an acorn cannula placed against the cervix or a balloon catheter positioned within the uterus (see Figs. 41-28.4 and 41-28.5). Tubal spill is evaluated through the laparoscope (Fig. 19-8). Indigo carmine dye is preferable to methylene blue, as the latter rarely may induce acute methemoglobinemia, particularly in patients with glucose-6-phosphate dehydrogenase deficiency. Laparoscopy allows both diagnosis and immediate surgical treatment of abnormalities such as endometriosis or pelvic adhesions. Laparoscopic ablation of endometriotic lesions or adhesions may increase subsequent pregnancy rates.

FIGURE 19-8



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Chromotubation seen at laparoscopy. Note the spill of blue dye from the fimbriated end of the fallopian tube onto the ovarian surface. *(Courtesy of Dr. Kevin Doody.)*

As laparoscopy is an invasive procedure, it is not advocated in place of HSG as part of the initial infertility evaluation. Exceptions include women with a history or symptoms suggestive of endometriosis or pelvic inflammation. However, even in these women a preliminary HSG may be informative (De Hondt, 2005).

If laparoscopy is clearly indicated, then hysteroscopy can also be performed while the patient is under anesthesia to evaluate the uterine cavity. Moreover, in operative hysteroscopic cases, laparoscopy can help direct surgery and avoid perforation, for example, during septal incision.

Laparoscopy also may be considered in patients who fail to conceive with clomiphene or gonadotropin ovulation induction. If pelvic disease is found and treated, progression to IVF may be avoided. With improvements in IVF success rates, this latter argument is

becoming less justifiable, as the cost of surgery well exceeds the cost of an IVF cycle.

Hysteroscopy

Endoscopic evaluation of the intrauterine cavity is the primary method for defining intrauterine abnormalities. Hysteroscopy can be performed in an office or operating room. With improved instrumentation, the ability to concurrently treat abnormalities in the office is increasing, however, substantially more extensive hysteroscopic surgery is possible in an operating room setting. A fuller discussion of hysteroscopy and its indications is found in atlas Section 41-35, Hysteroscopy.

CERVICAL FACTORS

The cervical glands secrete mucus that is normally thick and impervious to sperm and ascending infections. High estrogen levels at midcycle change the characteristics of this mucus, and it becomes thin and stretchy. Estrogen-primed cervical mucus filters out nonsperm components of semen and forms channels that help direct sperm into the uterus (Fig. 19-9B). Midcycle mucus also creates a reservoir for sperm, allowing ongoing release during the next 24 to 72 hours and extending the potential time for fertilization (Katz, 1997).

FIGURE 19-9

A. A ferning pattern is seen when periovulatory cervical mucus is spread and dried on a microscope slide. *(Courtesy of Dr. James C. Glenn.)* **B.** Examples of postcoital test slides. Slide 1: Columns within adequate cervical mucus help direct sperm into the uterine cavity. In patients with increasingly thick hostile mucus (slides 2 & 3), sperm display decreased motility.

Abnormalities in mucus production are most frequently observed in women who have undergone cryosurgery, cervical conization, or a loop electrosurgical excision procedure (LEEP) for treatment of an abnormal Pap smear. It has also been proposed that cervical infection can negatively impact mucus quality, however, the data in this area have been controversial. Implicated agents include *Chlamydia trachomatis* , *Neisseria gonorrhoeae* , *Ureaplasma urealyticum* , and *Mycoplasma hominis* (Cimino, 1993). Although there may be no advantage in terms of mucus quality, obtaining cultures for *C trachomatis* and *N gonorrhoeae* seems prudent to avoid causing ascending infection during HSG or intrauterine inseminations.

Postcoital Test

Also known as the Sims-Huhner test, this test can be performed to evaluate the presence of normal cervical mucus (Oei, 1995a, 1995b). A couple is requested to have intercourse on the day of ovulation. The woman is seen in the office within a few hours, and a sample of the cervical mucus is obtained from the cervical os with forceps or by aspiration. In the presence of high estrogen levels, mucus should be copious, stretchy, and relatively clear. Mucus should be able to be stretched to >5 cm. These qualities are summarized by the term *spinnbarkeit* . At least five motile sperm per high-power field should be visible under the microscope, although some authorities feel that a single, forward-moving sperm is adequate. There should be a minimal number of other cell types, such as inflammatory cells. When dried, the mucus should form a ferning pattern due to an increased salt concentration in the mucus prompted by increased preovulatory estrogen levels (Fig. 19-9A).

The most common reason for an abnormal test is improper timing. If mucus is scanty and thick, often termed *hostile* , then sperm

motility evaluation is futile, and the test should be repeated (Fig. 19-9B).

Despite the above discussion, the utility of the postcoital test is probably negligible in most circumstances. There is limited consensus on the definition of a normal test, and the predictive value for conception is poor (Oei, 1995b). Moreover, various approaches to improve an abnormal postcoital test have not convincingly increased pregnancy rates. In a prospective, randomized controlled trial, a normal postcoital test did not predict increased cumulative pregnancy rates (Oei, 1998).

Many infertility specialists recommend literally bypassing the cervix with intrauterine insemination in any woman with a history of cervical surgery, especially if she has noted a decrease in midcycle mucus production. The remaining utility of the postcoital test is for couples who will not consider intrauterine insemination or do not have intrauterine insemination readily available. It may also be useful in regions of the world in which more specific testing cannot be obtained, as a postcoital test will provide basic information regarding mucus production, appropriate intercourse practices, and presence of motile sperm.

Etiology of Infertility in the Male

Causes of male infertility can roughly be categorized as abnormalities of sperm production, abnormalities of sperm function, and obstruction of the ductal outflow tract.

NORMAL SPERMATOGENESIS

During evaluation of a male infertility patient, it is critical to understand the basics of male reproductive physiology. Analogous to the ovary, testes have two functions: the generation of mature germ cells (sperm) and the production of male hormones, primarily testosterone. The seminiferous tubules contain developing sperm and support cells called *Sertoli cells* or *sustentacular cells* (see Fig. 19-3C). The Sertoli cells form tight junctions that produce a blood-testis barrier. This avascular space within the seminiferous tubules protects sperm from antibodies and toxins, but also makes these cells dependent on diffusion for oxygen, nutrients, and metabolic precursors. Located between the seminiferous tubules are Leydig cells also called *interstitial cells* , which are responsible for steroid hormone production. In simplistic terms, Leydig cells are similar to the thecal cells of the ovary.

Unlike the ovary, testes contain stem cells that allow ongoing production of mature germ cells throughout a male's life. In a fertile male, approximately 100 to 200 million sperm are produced each day (Sigman, 1997). The process begins with a diploid (46,XY) spermatogonial cell, which grows and becomes a primary spermatocyte. The first meiotic division produces two secondary spermatocytes, and completion of meiosis results in four mature sperm with a haploid (23,X or 23,Y) karyotype (see Fig. 19-3C). During this developmental process, the majority of sperm cytoplasm is lost, mitochondria that provide energy are positioned in the midpiece of the sperm, and sperm develop flagella (see Fig. 19-3D).

Production of sperm requires approximately 70 days to complete. An additional 12 to 21 days is needed for sperm to be transported into the epididymis, where they further mature and develop motility (Heller, 1963; Hinrichsen, 1980; Rowley, 1970). It is important to realize that, due to this prolonged developmental period, the results of a semen analysis reflect events over the past 3 months, not a single point in time.

To fertilize an oocyte, human sperm must undergo a process known as *capacitation* . Capacitation results in sperm hyperactivation (an extreme increase in movement) as well as the ability of sperm to release acrosomal contents, which allow penetration of the zona pellucida.

Normal spermatogenesis is dependent on high local levels of testosterone. Luteinizing hormone (LH) from the anterior pituitary gland stimulates production of testosterone by the Leydig cells in the interstitium of the testes. Follicle-stimulating hormone (FSH) increases LH receptors on the Leydig cells, indirectly contributing to testosterone production. In addition, FSH increases production of sex hormone-binding globulin, also called androgen-binding protein. Androgen-binding protein binds testosterone and maintains high concentrations of this hormone in the seminiferous tubules (Sigman, 1997).

In addition to hormone levels, testicular volume often reflects spermatogenesis, and a normal volume is between 15 and 25 mL. The majority of this volume is provided by the seminiferous tubules, and therefore decreased testicular volume is a strong indicator of abnormal spermatogenesis.

Spermatogenesis is directed by genes on the Y chromosome with important contributions by autosomal genes, which have just

recently been elucidated. Therefore, genetic abnormalities may also adversely affect this process, as will be discussed later in this chapter.

Male fertility likely decreases modestly with age. A number of studies have demonstrated that pregnancy rates decrease and time to conception increases as male age increases. Studies of semen parameters across age have suggested that sperm concentration is maintained, however, sperm motility and morphology progressively worsen (Levitas, 2007). The clinical significance of this change is unclear (Kidd, 2001). In short, although advancing male age may have an impact on fertility, it is probably insignificant compared with the changes in women.

SEMEN ANALYSIS

Semen analysis is a core test in evaluation of male fertility status. For this test, the male is asked to refrain from ejaculation for 2 to 3 days, and a specimen is collected by masturbation into a sterile cup. If masturbation is not an option, then a couple can use specially designed Silastic condoms without lubricants. It is critical that the sample arrives in the laboratory within an hour of ejaculation to allow for optimal analysis.

The sample undergoes liquefaction, or thinning of the seminal fluid, due to enzymatic action from the liquid contribution of the prostate gland. This process takes 5 to 20 minutes and allows more accurate evaluation of the sperm contained in the seminal fluid. Ideally, two semen samples separated by at least a month should be analyzed. In practice, frequently only a single sample is analyzed if parameters are normal.

The reference values for the semen analysis are shown in Table 19-6 (World Health Organization, 1999). A clinician should remember a number of critical aspects with regard to this test. First, semen characteristics will vary across time in a single individual. Second, semen analysis results, particularly morphologic interpretation, will differ between laboratories. Therefore, reference ranges for the laboratory being used should be known. Note that the concept of "reference" range is more appropriate than "normal" range. Although total motile sperm count correlates with fertility, not all males with "normal" semen parameters display normal fertility (Guzick, 2001). The lack of absolute predictive value for this test is likely due to the fact that it does not provide information about sperm function, that is, the ultimate ability to fertilize an oocyte.

Table 19-6 Semen Analysis

Volume	>1.5 mL[a]
Count	>20 million/mL[a]
Motility	>50%[a]
Morphology	>30%[b]
	>14%[a] (Kruger's)[c]
WBCs	<1 million/mL[a]
Round cells	<5 million/mL[a]

WBCs = white blood cells.

[b] From World Health Organization, 1992, with permission.

[c] From Kruger, 1988, with permission.

Most semen analysis reports will indicate semen volume, pH, and presence or absence of fructose. Nearly 80 percent of semen volume comes from the seminal vesicles. The seminal fluid is alkaline and is thought to protect sperm from acidity present in prostatic secretions and in the vagina. Seminal fluid also provides fructose as an energy source for sperm. An acidic pH or lack of

fructose is consistent with obstruction of the efferent ductal system (Daudin, 2000).

Semen Volume

Low semen volume is often simply due to incomplete specimen collection or short abstinence interval. However, it may indicate partial obstruction of the vas deferens or retrograde ejaculation. Retrograde ejaculation follows failed closure of the bladder neck during ejaculation, allowing the seminal fluid to flow backwards into the bladder. Retrograde ejaculation should be suspected in men with diabetes mellitus, spinal cord damage, or a history of prostate or other retroperitoneal surgery, which may have produced nerve damage (Hershlag, 1991). Medications, particularly β-blockers, may contribute to this problem. A postejaculatory urinalysis can detect the presence of sperm in the bladder and confirm the diagnosis. If urine is properly alkalinized, these sperm are viable and can be retrieved to achieve pregnancy.

Sperm Count

A male partner may have normal sperm counts, *oligospermia* (low counts), or *azoospermia* (no sperm) (Jarow, 1989; Sharlip, 2002). Oligospermia is defined as a concentration of less than 20 million sperm per milliliter, with counts of less than 5 million per milliliter considered to be severe. The prevalence of azoospermia is approximately 1 percent of all men. Azoospermia may be due to obstruction in the outflow tract, termed obstructive azoospermia, such as that which occurs with absence of the vas deferens or severe infection. Azoospermia may also follow testicular failure (nonobstructive azoospermia). In the latter case, careful centrifugation and analysis may identify the presence of a small number of motile sperm adequate for use in IVF. Alternatively, this latter group may have viable sperm obtainable through either epididymal aspiration or testicular biopsy. Endocrine and genetic evaluation is indicated for men with abnormal sperm counts, as will be described later in this chapter.

Sperm Motility

Decreased sperm motility is termed *asthenospermia* . Some laboratories will distinguish between rapid (grade 3 to 4), slow (grade 2), and nonprogressive (grade 0 to 1) movement. Total progressive motility is the percentage of sperm exhibiting forward movement (grades 2 to 4). Asthenospermia has been attributed to prolonged abstinence, presence of antisperm antibodies, genital tract infections, or varicocele.

The hypo-osmotic swelling test can help to differentiate between dead and nonmotile sperm. Unlike dead sperm, living sperm can maintain an osmotic gradient. Thus, when mixed with a hypo-osmotic solution, living, nonmotile sperm with normal membrane function swell and coil as fluid is absorbed (Casper, 1996). Once identified, these viable sperm may be used for intracytoplasmic sperm injection.

Sperm Morphology

Abnormal sperm morphology is termed *teratospermia* . Many laboratories use the original classification in which normal morphology is characterized by over 50 percent of sperm exhibiting normal shape. More recently, Kruger and colleagues (1988) have developed strict criteria for defining normal morphology. Their studies defined a more detailed characterization of normal sperm morphology, with improved correlation with fertilization rates during IVF cycles. Their criteria require careful analysis of the shape and size of the sperm head, the relative size of the acrosome in proportion to the head, and characteristics of the tail, including length, coiling, or the presence of two tails (Fig. 19-10). Fertilization rates are highest with normal morphology greater than 14 percent. Significantly decreased fertilization rates are seen when normal morphology falls to less than 4 percent.

FIGURE 19-10

A. Normal sperm

Some types of abnormally formed spermatozoa. **A.** Normal sperm. **B.** Acrosomal defects. **C.** Head defects. **D.** Midpiece defects. **E.** Tail defects.

Round cells in the sperm sample may represent either leukocytes or immature sperm. White blood cells (WBCs) can be

distinguished from immature sperm using a variety of techniques, including a myeloperoxidase stain for WBCs (Wolff, 1995). True leukocytospermia is defined as the presence of greater than one million WBCs per milliliter and may indicate the presence of chronic epididymitis or prostatitis. In this scenario, many andrologists would consider empiric antibiotic treatment prior to obtaining a repeat semen analysis. A common protocol would include doxycycline at a dosage of 100 mg orally twice daily for 2 weeks. Alternative approaches include culture of any expressible discharge or of the semen sample.

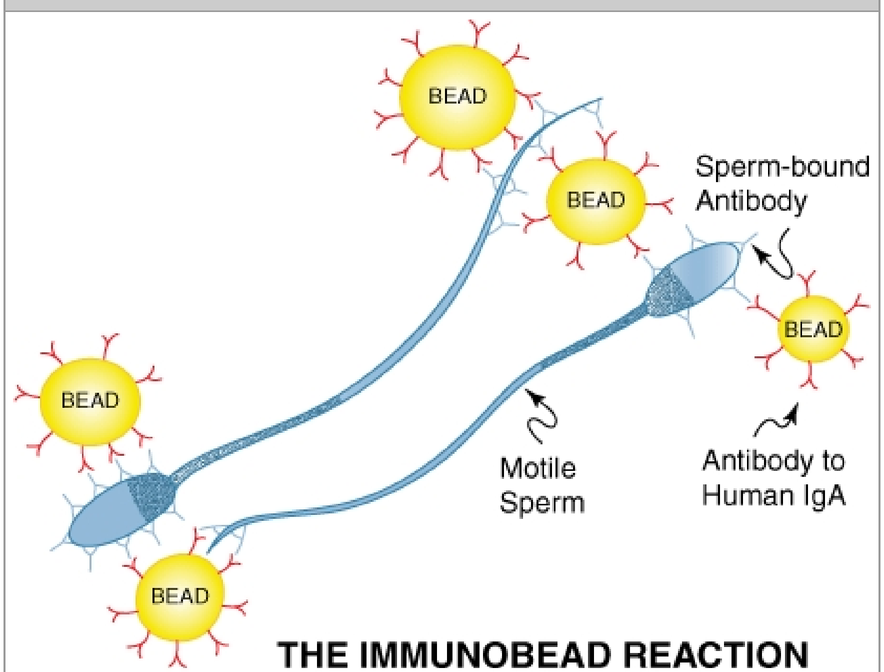
Unless a general obstetrician-gynecologist has developed a particular interest and expertise in the area of infertility, repeated abnormal semen analyses are an indication for referral to an infertility specialist. Although a referral may be made directly to a urologist, it may be more reasonable to have a couple be seen by a reproductive endocrinologist, as the female will also require evaluation. Treatment is likely to be more complex in these couples and will typically be directed to both partners. The reproductive specialist can determine the need for further referral of the male partner to a urologist for investigation of genetic, anatomic, hormonal, or infectious abnormalities.

ANTISPERM ANTIBODIES

Although antisperm antibodies may be detected in as many as 10 percent of men, controversy exists over the impact on fertility of antisperm antibodies (ASAs) in semen. These antibodies may be particularly prevalent following vasectomy, testicular torsion, testicular biopsy, or other clinical situations in which the blood-testis barrier is breached (Turek, 1994). It is currently felt that only IgG or IgA bound to the sperm head or midpiece are critical for decreasing fertilization capacity.

The most commonly employed assay contains immunobeads which are mixed with the sperm preparation. These beads will bind to antibodies present in a sperm sample. This mixture can be visualized under a standard microscope to look for beads binding to sperm (Fig. 19-11). Treatment historically included corticosteroids, but it is unclear that this approach improves fertility. Moreover, significant side effects, including aseptic necrosis of the hip, have been reported in treated patients.

FIGURE 19-11



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Immunoreactive beads bind to sperm carrying antibodies.

Current data suggest that antisperm antibodies do not need to be tested routinely as part of an infertility evaluation unless the

male partner has a clear risk factor for the presence of these antibodies. An exception would be those patients who will undergo IVF. Fertilization rates have been shown to be improved using intracytoplasmic sperm injection (ICSI) in an antibody-positive population.

ASSAYS OF SPERM FUNCTION

A wide variety of assays to test sperm function have been developed during the past few decades. The predictive significance of these assays is questionable, as they are based on highly nonphysiologic conditions, and results vary widely from infertility center to infertility center. Most are no longer used or are used only intermittently by infertility specialists. These tests are briefly described to provide more complete information to the general practitioner, however, they should not be considered part of a basic infertility evaluation.

Mannose Fluorescence Assay

The ability of sperm to recognize the zona pellucida of an oocyte is dependent on the presence of a number of proteins and sugars on the zona surface, including the sugar mannose. Acrosomal mannose-ligand receptor activity has been shown to correlate with IVF pregnancy rates (Benoff, 1993).

For this receptor assay, mannose residues in bovine serum albumin are modified so that they release fluorescence. A capacitated sperm sample from a patient is mixed with this fluorescent preparation. In a parallel experiment, sperm from a known fertile donor is mixed with the same fluorescent preparation in a separate dish. The patient's binding pattern is compared with the pattern obtained with the fertile male sample.

Hemizona Assay

The hemizona assay is a technique for analyzing the ability of a sperm sample to bind to the zona pellucida. Human oocytes are bisected (to prevent fertilization) and are mixed either with the partner's sperm or with fertile donor sperm. The hemizona index is calculated by dividing the number of patient sperm bound by the number of control sperm bound and multiplying by 100 (Burkman, 1988).

Sperm Penetration Assay

The sperm penetration assay is performed by mixing capacitated sperm with hamster oocytes. The zona pellucida typically prevents cross-species sperm binding and must first be removed from these test oocytes. The number of oocytes that are penetrated by sperm is calculated. The presumption is that more oocytes will be penetrated by sperm from fertile men than sperm from infertile men (Smith, 1987b).

Acrosomal Reaction

Penetration of an oocyte requires that sperm undergo an acrosomal reaction, during which the enzymatic contents of the acrosome are released on interaction with the oocyte membrane. Various methods can be used to induce the acrosomal reaction in a patient's sperm sample. The percentage of sperm which undergo the reaction is compared with that of a control sample (Sigman, 1997).

HORMONAL EVALUATION OF THE MALE

Hormonal testing in the male is analogous to endocrine testing in an anovulatory female (see Table 16-7). Essentially, abnormalities may be due to central defects in hypothalamic-pituitary function or to defects within the testes. Most urologists will defer testing unless a sperm concentration is less than 10 million/mL. Testing will include measurements of serum FSH and testosterone (T) levels. Elevated FSH and low T levels providing evidence of testicular failure. Alternatively, low FSH and low T levels are consistent with hypothalamic dysfunction, such as idiopathic hypogonadotropic hypogonadism or Kallman syndrome.

Unfortunately, most men with oligospermia will be found to have varying degrees of irreversible primary testicular failure. Nevertheless, it is important to determine whether testosterone replacement is indicated in this patient population. Normal spermatogenesis requires high levels of intratesticular testosterone, which cannot be achieved with exogenous testosterone. Furthermore, many of these men will lack spermatogonial stem cells. Therefore, testosterone replacement will not rescue sperm production. However, replacement will provide other benefits, such as improved libido and sexual function, and maintenance of muscle mass and bone density, as well as a general sense of well-being.

Additional hormonal testing may be included as part of an evaluation of the infertile male. Elevated serum prolactin levels and thyroid dysfunction impact spermatogenesis and are the most likely endocrinopathies to be detected (Sharlip, 2002; Sigman, 1997).

GENETIC TESTING OF THE MALE

Genetic abnormalities are a relatively common cause of abnormal semen characteristics. Approximately 15 percent of azoospermic men and 5 percent of severely oligospermic men will have an abnormal karyotype. Although genetic abnormalities cannot be corrected, they may have implications for the health of the patient or their offspring, and therefore should be pursued when indicated by poor semen analysis results.

Karyotype testing should be obtained on all azoospermic and severely oligospermic men. The lower limit in sperm concentration that prompts karyotype testing varies between practitioners, but lies between 3 and 10 million sperm per milliliter.

Klinefelter syndrome (47,XXY) will be a frequent finding. Klinefelter syndrome is observed in about 1 in 500 men in the general population and accounts for 1 to 2 percent of male infertility. Classically, these men are tall, undervirilized, and have gynecomastia and small, firm testes (De Braekeleer, 1991). As the phenotype varies widely, lack of these characteristics should not preclude chromosomal evaluation. Conversely, a clinician should strongly consider obtaining karyotype testing in any male with these characteristics. Autosomal abnormalities will also be found in a subset of men with severe oligospermia.

A patient with severely decreased sperm counts and a normal karyotype should be offered testing for microdeletion of the Y chromosome. Up to 15 percent of men with severe oligospermia or azoospermia will have small deletions in the region of the Y chromosome, termed the *azoospermia factor region* (AZF). If the deletion is within the AZFa or AZFb subregions, then it is unlikely that viable sperm can be recovered for use in IVF. Most men with an AZFc deletion will have viable sperm at biopsy. However, these deletions should be presumed to be inherited by their offspring. The clinical significance of microdeletions in the recently identified AZFd region is unknown, as these patients have apparently normal spermatogenesis (Kent-First, 1999; Pryor, 1997).

Patients may decline testing for microdeletion of the Y chromosome for a variety of reasons. Beyond infertility, there are no known health risks associated with these deletions. Many couples with azoospermia will chose to use donor sperm, and thus identification of this mutation may not be pertinent. Other couples reason that if the husband is able to have a child despite this deletion, there is no significant disadvantage if the abnormality is transmitted to any offspring.

Obstructive azoospermia may be due to congenital bilateral absence of the vas deferens (CBAVD). Approximately 70 to 85 percent of men with CBAVD will be found to have mutations in the cystic fibrosis transmembrane conductance regulator gene (*CFTR* gene), although not all will have clinical cystic fibrosis (Oates, 1994; Ratbi, 2007). Conversely, essentially all men with clinical cystic fibrosis will have CBAVD. Fortunately, testicular function in these men is usually normal, and adequate sperm may be obtained by epididymal aspiration to achieve pregnancy through IVF. Careful genetic counseling and testing the female partner for carrier status is critical in these situations.

TESTICULAR BIOPSY

Evaluation of a severely oligospermic or azoospermic male may include either open or percutaneous testicular biopsy to determine whether viable sperm are present in the seminiferous tubules (Sharlip, 2002). For example, even men with testicular failure diagnosed by elevated serum FSH levels may have adequate sperm on biopsy for use in intracytoplasmic sperm injection. The biopsy specimen can be cryopreserved for future extraction of sperm during an IVF cycle. Thus, the biopsy may have diagnostic, prognostic, and therapeutic value.

CONCLUSION

Figure 19-12 provides an algorithm for the evaluation of an infertile couple. Details will vary between practitioners and will be affected by patient presentation. In general, the female partner should have some form of testing to confirm ovulation and should undergo hysterosalpingography, whereas the male partner should have semen analysis performed. In older women, it is crucial to evaluate an early follicular FSH level to ensure adequate follicular reserves. A subset of couples will decline hysterosalpingography and semen analysis if the woman has a clear ovulatory defect. These couples should be reminded that there is a relatively high incidence of couples having two abnormalities, one of which would be missed with this approach. These patients may be treated, but should be strongly encouraged to complete the evaluation if they do not conceive within a few months. Options for treatment are discussed in Chapter 20.

TREATMENT OF THE INFERTILE COUPLE: INTRODUCTION

Infertility results from diseases of the reproductive system that impair the body's ability to perform basic reproduction function. Ten to 15 percent of the reproductive-aged population is infertile, and men and women are equally affected.

Infertility treatment is a complex process influenced by numerous factors. Important considerations include duration of infertility, a couple's age (especially the female's), and diagnosed cause. Additionally, the level of distress experienced by a couple should be taken into account.

In general, the first step involves identification of a primary cause and contributing factors, and treatment is aimed at their direct correction. Most are treated with conventional therapies such as medication or surgery. In many cases, therapy can begin without a complete evaluation, especially if a cause is obvious. However, if pregnancy does not quickly follow, then more thorough testing is required.

In contrast, it is common for evaluation not to yield a satisfactory explanation or to identify causes that are not amenable to direct correction. Recent advances in assisted reproduction have allowed for treatment of such cases. These approaches, however, are not without disadvantages. For example, appropriate treatments may pose ethical dilemmas for couples or their physician. Additionally, infertility treatment can be a financial burden, a significant source of emotional stress, or both.

An infertility specialist should not dictate treatment, but should offer and explain therapy options, which may include expectant management or even adoption.

LIFESTYLE THERAPIES

Environmental Factors

Increasing information suggests that some male and female infertility may result from environmental contaminants or toxins (Giudice, 2006). Exposures to endocrine-disrupting chemicals such as dioxins and polychlorinated biphenyls, agricultural pesticides and herbicides, phthalates (used in making plastics), and bisphenol A (used in the manufacture of polycarbonate plastic and resins) have been shown in wildlife and laboratory animals to be reproductive toxicants. These exposures may occur in utero, neonatally, or later.

Although direct links to infertility in humans are not conclusive, clinicians should counsel patients that environmental exposures to toxic substances should be avoided if possible. Currently, these cautions should be discussed carefully to avoid alarm.

Smoking

At least one-fifth of reproductive-aged men and women in the United States smoke cigarettes (Centers for Disease Control and Prevention, 2005) (Table 20-1). Several comprehensive reviews have summarized cumulative data on cigarette smoking and female fecundity, and all support the conclusion that smoking has an adverse impact (see Chap. 19, Social) (Practice Committee of the American Society of Reproductive Medicine, 2004c). Moreover, smoking's negative effects on female fecundity do not appear to be overcome by assisted reproductive technologies (ART). A 5-year prospective study of 221 couples found that the risk of failing to conceive with ART was more than doubled in smokers. Each year that a woman smoked was associated with a 9-percent increase in the risk of unsuccessful ART cycles (Klonoff-Cohen, 2001).

Table 20-1 Public Knowledge of the Risks of Smoking	
Smoking Risk	**Knowledge of Risk**
Lung cancer	99%
Respiratory	99%
Heart disease	96%
Miscarriage	39%
Osteoporosis	30%
Ectopic pregnancy	27%
Infertility	22%
Early menopause	17%

From American Society of Reproductive Medicine, 2004c, with permission.

The effect of smoking on male fertility is more difficult to discern. Male smokers often have comparatively reduced sperm concentrations and motility (Ramlau-Hansen, 2007). However, parameters often remain within the normal range.

Smoking is associated with an increased miscarriage rate in both natural and assisted conception cycles. The mechanism for this has not been elucidated, but the vasoconstrictive and antimetabolic properties of some components of cigarette smoke such as nicotine, carbon dioxide, and cyanide may lead to placental insufficiency. In addition, smoking in pregnant women is associated with an increased risk of trisomy 21 that results from maternal meiotic nondisjunction (Yang, 1999).

For these reasons, smoking should be discouraged for both male and female partners in couples with a history of infertility or recurrent miscarriage. When behavioral approaches fail, use of medical adjuncts such as nicotine replacement therapy or bupropion (Zyban, GlaxoSmithKline, Philadelphia, PA) may prove effective (see Table 1-20). Nicotine gum carries a category C classification, whereas the other preparations are designated as category D. The only non-nicotine Food and Drug Administration (FDA)-approved agent is bupropion, which carries a category B designation. Although studies of these agents in pregnant women have been limited, ideally pharmacologic smoking cessation therapies are best used prior to conception.

Alcohol

Alcohol consumption is widespread and increasing in many countries. Although it is well known that chronic alcohol abuse during pregnancy may lead to fetal alcohol syndrome, the impact on fertility has been less well studied (Homan, 2007). Retrospective investigations have generally found that moderate alcohol intake in women has no significant effect on fertility, whereas a high intake has been associated with reduced fecundability. However, one prospective study of Danish couples attempting pregnancy did demonstrate a decreased fecundability even among women with a weekly alcohol intake of five or fewer drinks (Jensen, 1998). This finding needs further corroboration, but it seems reasonable to encourage women to avoid alcohol when they are trying to become pregnant.

Caffeine

Caffeine is one of the most widely used pharmacologically active substances in the world. Recent studies have suggested that a positive dose-response relationship between caffeine and impaired fertility does exist. Hassan and Killick (2004) determined that women who consumed seven or more cups of coffee or tea per day were 1.5 times more likely to be subfertile. Significant caffeine consumption has also been linked to an increased abortion risk and is discussed again in Chapter 6, Caffeine. Accordingly, recommendations of caffeine intake moderation by infertile women seem prudent.

Weight Optimization

OBESE WOMEN

Ovarian function is dependent on weight. Low body fat content is associated with hypothalamic hypogonadism. In contrast, central body fat is associated with insulin resistance and contributes to ovarian dysfunction in many women with polycystic ovarian syndrome.

Lifestyle modification in overweight infertile women with PCOS leads to a reduction of central fat and improved insulin sensitivity, decreased hyperandrogenemia, lowered luteinizing hormone (LH) concentrations, and restoration of normal fertility in many cases (Kiddy, 1992; Hoeger, 2001). Even a 5- to 10-percent reduction in body weight has been shown to be successful in these women (Table 20-2) (Pasquali, 1989; Kiddy, 1992). Apart from diet, exercise can also improve insulin sensitivity. Weight loss and exercise are inexpensive and should be recommended as first-line management of anovulation in obese women with PCOS.

Table 20-2 Efficacy of Lifestyle Intervention in Anovulatory Infertile Women

Parameter	**Completed, *n* = 67 (Mean Â± SD or %)**	**Drop-Out, *n* = 20 (Mean Â± SD or %)**
BMI, basal	37.4 Â± 6.9	35.9 Â± 4.1
PCOS status	79%	72%
Anovulatory at baseline	81%	75%
Change in BMI	â€“3.7 Â± 1.6	â€“0.4 Â± 1.4[a]
Resumed spontaneous ovulation	90%	None
Pregnancies (cumulative: spontaneous or assisted reproductive technologies)	77%	None

The original cohort included 87 infertile obese women, most of whom had PCOS, and treatment consisted of a long-term lifestyle intervention program, including physical activity and hypocaloric diet. Those who completed were compared with those who dropped out.

[a] $p < .05$.

From Pasquali, 2006, with permission.

Although pharmacologic options can effectively treat anovulation if weight cannot be lost, it should also be noted that obesity is a significant risk factor for obstetric and perinatal complications. Therefore, strong consideration should be given to delaying treatments in morbidly obese women until their body mass index (BMI) can be reduced below 40 kg/m^2 . This is especially true if treatments involve surgery or risk of multifetal gestation.

UNDERWEIGHT WOMEN

Although obesity is more commonly encountered, undernutrition can also be a problem. The reproductive axis is closely linked to nutritional status and inhibitory pathways suppress ovulation in subjects with significant weight loss. Anorexia nervosa and bulimia nervosa affect up to 5 percent of reproductive-aged women and may cause amenorrhea and infertility (see Chap. 16, Eating Disorders). In those who do conceive, there is increased likelihood of miscarriage (Table 20-3). Fortunately, recovery may follow minimal acquisition of weight because energy balance has a more important effect than body fat mass.

Table 20-3 Relation of Comorbid Mental Disorders to Amenorrhea at Baseline and 10- to 15-Year Follow-Up among 173 Women with Bulimia Nervosa												
	Current Amenorrhea						Amenorrhea Over 10- to 15-Year Follow-Up					
	Total	Rate		Analysis			Total	Rate		Analysis		
Lifetime Mental Disorder	*n*	*n*	%	X^2	df	*p*	*n*	*n*	%	X^2	df	*p*
Anorexia nervosa				7.89	2	<.02				43.48	2	<.001
Present	59	16	27.1				50	43	86.0			
Subthreshold	23	4	17.1				19	9	47.4

Exercise

Physical activity has been demonstrated to have numerous health benefits. The relationship between exercise and fertility, however, is not straightforward. Competitive female athletes often experience amenorrhea, irregular cycles or luteal dysfunction, and infertility (see Chap. 16, Exercise-Induced Amenorrhea). This may be related not specifically to physical activity itself, but rather to low body fat content or physical stress associated with competition.

At this time, insufficient data exist to support or discourage physical activity in infertile women in the absence of documented ovarian dysfunction associated with low body weight.

Nutrition

In the absence of obesity or significant undernutrition, the role of diet in infertility is unclear. High-protein diets and gluten intolerance have been investigated as underlying causes in women (Meloni, 1999). In men, dietary antioxidants have been proposed as a potential way to improve male reproductive outcomes by reducing oxidative damage in sperm DNA. Additionally, the nutritional supplement, carnitine, had been often touted as having potential benefit for male infertility. This finding has not been confirmed by randomized, prospective trial (Sigman, 2006).

Despite a lack of conclusive benefits to nutritional supplements or diet modification in infertile couples, it does seem reasonable to recommend daily multivitamin supplementation to both. Folic acid is contained in most multivitamins, and daily doses of 400 μg orally are recommended for women attempting pregnancy to reduce the incidence of neural-tube defects in their fetuses (American College of Obstetricians and Gynecologists, 2003)

Stress Management

Stress has been implicated in reproductive failure. Although severe stress can result in anovulation, less significant stress may also play a role, but a mechanism has yet to be defined. Patients with higher stress levels have been found to have lower pregnancy rates when undergoing in vitro fertilization (IVF) treatments (Thiering, 1993). Consideration should be given to screening all infertile couples for evidence of anxiety or depression. Although pharmacologic management of stress is not typically recommended during infertility treatments, a "mind/body" approach that combines psychological counseling and meditation may be considered for those patients manifesting high levels of anxiety (Domar, 1990).

CORRECTION OF AN IDENTIFIED CAUSE

Correction of Ovarian Dysfunction

HYPERPROLACTINEMIA

Prolactin is a pituitary hormone that plays an important role in a variety of reproductive functions, and elevated levels are commonly encountered in clinical endocrinology (see Chap. 15, Hyperprolactinemia). If hyperprolactinemia is found, then physiologic, pharmacologic, or other secondary causes of hormone hypersecretion should be sought (see Table 12-3). In the absence of hypothyroidism or a pharmacologic cause of hyperprolactinemia, imaging studies should be performed to identify microadenoma or macroadenoma of the pituitary gland.

Dopamine agonists are the primary treatment of hyperprolactinemia (see Chap. 15, Treatment of Pituitary Adenomas). Surgical therapies should only be considered with prolactin-secreting adenomas resistant to medical therapy. If hyperprolactinemia is not associated with a pituitary lesion or if a lesion is less than 10 mm (microadenoma), then dopamine-agonist therapy is stopped during pregnancy. In these women, the risk of tumor expansion is low (Molitch, 1999). If the tumor size is 10 mm or larger (macroadenoma), then bromocriptine (Parlodel, Novartis Pharmaceuticals, East Hanover, NJ) use is advised during pregnancy to avoid significant tumor growth.

HYPOTHYROIDISM

Thyroid disorders are prevalent in reproductive-aged individuals and affect women four to five times more frequently than men. Clinical hypothyroidism is associated with changes in cycle length and amount of bleeding. Specifically, oligomenorrhea and amenorrhea are frequent findings. Although ovulation and conception can still occur in those with mild hypothyroidism, treatment with thyroxine usually restores a normal menstrual pattern and enhances fertility.

Subclinical hypothyroidism may also be associated with ovarian dysfunction (Strickland, 1990). Lincoln and colleagues (1999) found a 2-percent incidence of elevated thyroid-stimulating hormone (TSH) levels in 704 asymptomatic women seeking evaluation for infertility. Correction of hypothyroidism in those with ovarian dysfunction and elevated TSH levels led to pregnancy in 64 percent of patients. Although there is a possible effect on fertility, the effects of subclinical hypothyroidism on pregnancy outcomes is unclear. Therefore, early detection and treatment of hypothyroidism of any degree in women seeking treatment for infertility is advised.

OVULATION INDUCTION

Ovarian dysfunction is the most common indication for the use of medications to induce ovulation. These agents can also be used in ovulatory women to increase the likelihood of pregnancy in couples with other causes of infertility or unexplained infertility. Use of these medications in this manner has been referred to as superovulation (SO), ovulation enhancement, or controlled ovarian hyperstimulation (COH). In contrast, we prefer the term *"ovulation induction"* to describe treatment with medications to stimulate normal ovulation in women with ovarian dysfunction.

Frequent causes of ovarian dysfunction include PCOS and diminished ovarian reserve. Less often, central (hypothalamic or pituitary) disorders or thyroid dysfunction can result in infertility. Rarely, ovarian tumors or adrenal abnormalities lead to abnormal ovarian function. Treatment of ovarian dysfunction should be based on the identified cause as well as the results of any prior attempted treatments.

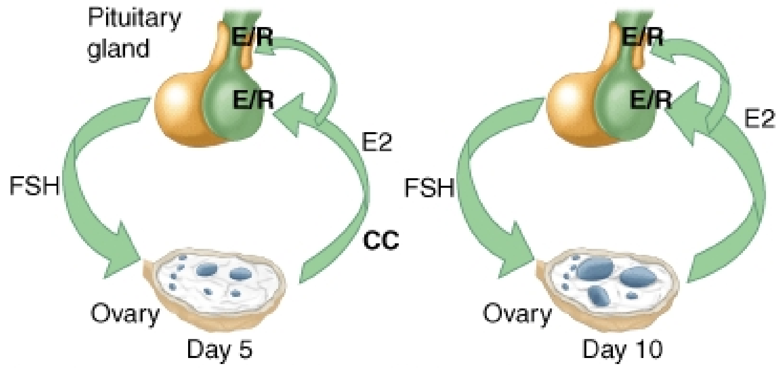
CLOMIPHENE CITRATE

Pharmacologic Effects

Clomiphene citrate (CC) is the initial treatment for most anovulatory infertile women. Chemically similar to tamoxifen, CC is a nonsteroidal triphenylethylene derivative that demonstrates both estrogen agonist and antagonist properties. Antagonist properties predominate except at very low estrogen levels. As a result, negative feedback that is normally produced by estrogen in the hypothalamus is reduced (Fig. 20-1). Gonadotropin-releasing hormone (GnRH) secretion is improved and stimulates pituitary gonadotropin release. The resulting increase in follicle-stimulating hormone (FSH), in turn, drives ovarian follicular activity.

FIGURE 20-1

Clomiphene Citrate Treatment



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Effect of clomiphene citrate (**CC**) administration. Administration leads to estrogen receptor (**ER**) depletion at the level of the pituitary and mediobasal hypothalamus. As a result, estrogen-negative feedback is interrupted centrally and follicle-stimulating hormone (**FSH**) secretion increases from the anterior pituitary, leading to maturation of multiple follicles. By the late follicular phase, because of clomiphene citrate's long retention within tissues, ER depletion continues centrally. As a result, increased estradiol (**E2**) secretion from the ovary is not capable of normal negative feedback on FSH release. This leads to a growth of multiple dominant follicles and multiple ovulations. *(Redrawn from Casper, 2003, with permission.)*

Tamoxifen has also been used successfully for ovulation induction. However, it is not approved by the FDA for this indication and has not been demonstrated to have significant advantage compared with CC.

Administration

Clomiphene citrate is administered orally, typically starting on the third to fifth day after the onset of spontaneous or progestin-induced menses. Ovulation rates, conception rates, and pregnancy outcome are similar regardless of whether treatment begins on cycle day 2, 3, 4, or 5. Prior to therapy, sonography is advised to exclude signs of significant spontaneous follicular maturation or residual follicular cysts. A pregnancy test is also indicated after spontaneous menses. Although, not a proven teratogen, CC is classified as category X by the FDA and thus, is contraindicated in suspected or documented pregnancy.

The dose required to achieve ovulation correlates with body weight, although there is no reliable way to accurately predict which dose will be required in an individual woman (Lobo, 1982). Consequently, CC is titrated empirically to establish the lowest effective dose for each individual patient. Treatment typically begins with a single 50-mg tablet daily for 5 consecutive days. Doses are increased by 50-mg increments in subsequent cycles until ovulation is induced. The dose of clomiphene citrate should not be increased if normal ovulation is confirmed, and lack of pregnancy alone does not justify an increase in dose.

The effective dose of CC ranges from 50 mg/d to 250 mg/d, although doses in excess of 100 mg/d are not approved by the FDA. Some studies have suggested that adjunctive therapy with glucocorticoids may benefit some patients not responsive to CC alone. This therapy may be empiric or individualized based on elevated dehydroepiandrosterone sulfate (DHEAS) levels.

In general, women failing to ovulate with 100 mg/d dosing or failing to conceive following 3 to 6 months of ovulatory response to CC should be considered candidates for alternative treatments. In a retrospective study including 428 women who received CC for ovulation induction, 84.5 percent of pregnancies achieved with treatment occurred during the first three ovulatory cycles (Gysler, 1982).

Insulin-Sensitizing Agents

Although PCOS appears to be a heterogeneous disorder, many women with this condition exhibit insulin resistance (see Chap. 17, Ovarian Hyperthecosis and HAIRAN Syndrome). Insulin resistance leads to compensatory hyperinsulinemia and dyslipidemia.

Given the strong evidence that hyperinsulinemia plays a pivotal pathogenic role in development of PCOS, it is reasonable to assume that interventions that reduce circulating insulin levels in women with PCOS may restore normal reproductive endocrine function. As discussed, weight loss, nutrition, and exercise have clearly led to reduced hyperinsulinemia with resolution of hyperandrogenism, and in some cases, resumption of ovulatory function in overweight women with PCOS. However, women may be poorly compliant, and weight loss is rarely maintained over time.

Recently, a new class of oral antidiabetic compounds, *insulin-sensitizing agents,* has been developed, which in early studies show promise in the treatment of PCOS. When administered to insulin-resistant patients, these compounds act to increase target tissue responsiveness to insulin, thereby reducing compensatory hyperinsulinemia (Antonucci, 1998). Current insulin-sensitizing agents include the biguanides and thiazolidinediones (see Chap. 17, Insulin-Sensitizing Agents).

Preliminary studies suggested that the biguanide, metformin (Glucophage, Bristol-Myers Squibb, New York, NY), 500 mg orally three times daily or 850 mg twice daily with meals, administered to women with PCOS increased the frequency of spontaneous ovulation, menstrual cyclicity, and ovulatory response to CC (Nestler, 1998; Palomba, 2005; Vandermolen, 2001). However, in contrast to those initial studies, a recent, large, prospective, randomized, multi-center trial does not support the hypothesis that metformin, either alone or in combination with CC, improves the rate of live birth in women with PCOS (Legro, 2007).

Gonadotropins

Clomiphene citrate is easy to use and leads to ovulation in the vast majority of patients, but pregnancy rates are disappointing (50 percent or less) (Hammond, 1983; Raj, 1977; Zarate, 1971). Lower-than-expected pregnancy rates with CC have been attributed to its long half-life and peripheral anti-estrogenic effects, mainly on the endometrium and cervical mucus. In such individuals, who are often classified as "clomiphene resistant", the next step is traditionally the administration of exogenous gonadotropin preparations via injections.

As with CC, the goal of ovulation induction with gonadotropins is simply to normalize ovarian function. Ideally, the dosage used should be the minimum required to cause normal development of a single dominant follicle. Because the response to gonadotropins can vary greatly from individual to individual and even from cycle to cycle, intensive monitoring is required to adjust dosage and timing of ovulation.

Gonadotropin preparations vary in terms of their source (urinary or recombinant) and the presence or absence of LH activity. Traditional urinary-derived human menopausal gonadotropin (hMG) preparations are extracted and purified from the urine of postmenopausal women, and their active components are both FSH and LH. The primary source of the LH activity is human chorionic gonadotropin (hCG), although significant LH is also present in the older, non-highly-purified hMG products (Filicori, 2002). Highly purified urinary preparations allow for administration via the subcutaneous route with minimal or no reaction at the injection site. Alternatives to hMG include highly purified urinary gonadotropin preparations and purified recombinant FSH (Table 20-4).

Table 20-4 Gonadotropin Preparations Used for Ovulation Induction					
Name	**Manufacturer**	**Product Type**	**FSH Activity**	**LH Activity**	**hCG Activity**
Bravelle	Ferring, Suffern, NY	Vial	Highly purified urinary	Minimal	Minimal
Fertinex[a]					
Follistim	Organon, Roseland, NJ	Pen or vial	Highly purified recombinant	None	None
Gonal-f	Serono, Rockland, MA				
Menopur	Ferring, Suffern, NY	Vial	Highly purified urinary	Minimal	Highly purified urinary
Repronex	Ferring, Suffern, NY	Vial	Urinary	Urinary	Urinary
Pergonal[a]					
Humagon[a]					

FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone.

[a] No longer available.

Both LH and FSH activity are required for normal ovarian steroidogenesis and follicular development. In many cases, pure FSH preparations can be used because of adequate endogenous LH production. However, for ovulation induction in patients with hypogonadotropic amenorrhea, LH activity must be provided from an exogenous source. Options include hMG, recombinant LH, and low-dose (diluted) urinary or recombinant hCG. Ovulation induction in women with PCOS can be performed either with FSH-only containing products or those containing both LH and FSH activity. At present, data do not support the superiority of one preparation over another.

Most clinicians begin ovulation induction attempts at a low dosage (50 to 75 IU/d) of gonadotropins and gradually increase the dose if no ovarian response (as assessed by serum estradiol measurements) is noted after several days (Fig. 20-2). This is referred to as a "step-up" protocol (Fig. 20-3). A "step-down" protocol can also be used with the advantage of a decreased duration of stimulation. However, the risk of excessive ovarian response, such as development of multiple follicles or ovarian hyperstimulation syndrome, may be increased with this approach. With either approach, if a patient fails to conceive, subsequent cycles may be started at higher dosages based on prior response.

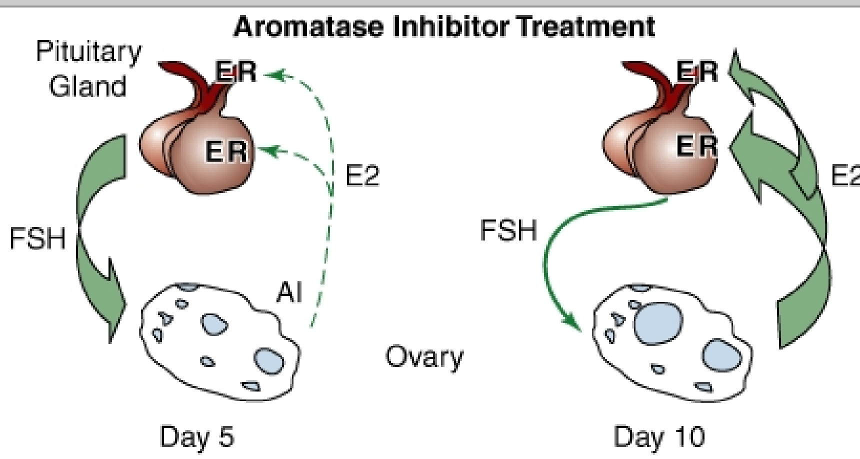
In general, results of gonadotropin stimulation in women with PCOS are less successful than in patients with hypogonadotropic amenorrhea (Balen, 1994). Women with PCOS have ovaries that are highly sensitive to gonadotropin stimulation and have a higher risk of excessive ovarian response and multifetal pregnancy than those with normal ovaries (Farhi, 1996).

Aromatase Inhibitors

Gonadotropins are associated with more effective ovulation induction and higher pregnancy rates than CC, but are expensive and carry higher risks for ovarian hyperstimulation syndrome and multifetal gestation. Accordingly, aromatase inhibitors have been investigated as new ovulation-inducing agents (Fig. 20-4). These agents were originally developed for breast cancer treatment and effectively inhibit *aromatase,* a cytochrome P-450 hemoprotein that catalyzes the rate-limiting step in estrogen production. Aromatase inhibitors are orally administered, easy to use, and relatively inexpensive with minor side effects.

FIGURE 20-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Effect of aromatase inhibitor (**AI**) administration. Administration suppresses ovarian estradiol (**E2**) secretion and reduces estrogen-negative feedback at the pituitary and mediobasal hypothalamus. Increased follicle-stimulating hormone (**FSH**) secretion from the anterior pituitary stimulates growth of multiple ovarian follicles. Later in the follicular phase, the effect of the aromatase inhibitor is reduced, and E2 levels increase as a result of follicular growth. Because aromatase inhibitors do not affect estrogen receptors (**ER**) centrally, the increased E2

levels result in normal negative feedback on FSH secretion. Follicles smaller than the dominant follicle undergo atresia, with resultant monofollicular ovulation in most cases. *(Redrawn from Casper, 2003, with permission.)*

The most widely used aromatase inhibitor to induce ovulation in anovulatory and ovulatory infertile women is letrozole (Femara, Novartis Pharmaceuticals, East Hanover, NJ). Compared with CC, its use is associated with a thicker endometrium and a trend toward higher pregnancy rates following ovulation induction. When used in combination with gonadotropins, letrozole leads to lower gonadotropin requirements and pregnancy rates comparable with gonadotropin treatment alone (Mitwally, 2004; Casper 2003). The typical dosage used is 2.5 to 5 mg orally daily for 5 days.

Data suggesting that letrozole use for infertility treatment might be associated with a higher risk of congenital cardiac and bone malformations in the newborn are contradictory (Biljan, 2005; Tulandi, 2006). However, in November 2005, the manufacturer issued a statement to physicians worldwide advising that letrozole use in premenopausal women, specifically its use for ovulation induction, is contraindicated. As a result, it is not likely that letrozole will gain widespread acceptance for ovulation induction in the near future. Well-designed randomized prospective trials confirming safety are needed.

A second aromatase inhibitor, anastrozole, is of the same compound class as letrozole and has also been approved for treatment of women with breast cancer. Only a few randomized studies have been completed evaluating this agent for ovulation induction (Al-Omari, 2004; Sipes, 2006). At this time, no concerns have been raised regarding its teratogenicity (Casper, 2007). Experience with anastrozole (Arimidex, AstraZeneca, Wilmington, DE) in ovulation induction at this time is limited, however. Ideal dosage requirements are currently unknown.

COMPLICATIONS OF FERTILITY DRUGS

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) is a clinical symptom complex associated with ovarian enlargement resulting from exogenous gonadotropin therapy (Fig. 20-5). Symptoms may include abdominal pain and distension, ascites, gastrointestinal problems, respiratory compromise, oliguria, hemoconcentration, and thromboembolism. These symptoms may develop during ovulation induction or in early pregnancies that were conceived through exogenous ovarian stimulation.

FIGURE 20-5

A. Transvaginal sonogram of ovaries with multiple large cysts secondary to ovarian hyperstimulation syndrome. Ovaries are enlarged and meet in the midline. Ascites surrounds these enlarged ovaries. **B.** Color Doppler transvaginal sonography is often performed to exclude torsion in these patients.

Pathophysiology

The etiology of OHSS is complex, but hCG, either exogenous or endogenous (derived from a resulting pregnancy), is believed to be an early contributing factor. Development of OHSS involves increased vascular permeability with loss of fluid, protein, and electrolytes into the peritoneal cavity, and leads to hemoconcentration. Increased capillary permeability is felt to result from vasoactive substances produced by the corpus luteum. Vascular endothelial growth factor (VEGF) is believed to play a major role, and angiotensin II may also be involved. Hypercoagulability may be related to hyperviscosity following hemoconcentration or may be secondary to the high estrogen levels present with a resulting increase in coagulation factors. Predisposing factors for OHSS include multifollicular ovaries such as with PCOS, young age, high estradiol levels, and pregnancy.

Diagnosis and Treatment

Abdominal pain is prominent and caused by ovarian enlargement together with accumulation of peritoneal fluid. Although sonographic examination of women with OHSS usually reveals enlarged ovaries with numerous follicular cysts and ascites, OHSS is a clinical diagnosis. Several different classification schemes have been proposed to categorize the severity of this syndrome (Table 20-5).

Table 20-5 Classification and Staging of Ovarian Hyperstimulation Syndrome
Grade 1: Abdominal distention/discomfort
Grade 2: Grade 1 plus nausea and vomiting or diarrhea Ovaries enlarged 5â€“12 cm
Grade 3: Sonographic evidence of ascites
Grade 4: Clinical evidence of ascites or hydrothorax or difficulty breathing
Grade 5: All of the above plus decreased blood volume, hemoconcentration, diminished renal perfusion and function, and coagulation abnormalities

From Whelan, 2000, with permission.

Treatment of OHSS is generally supportive. Paracentesis is typically performed transvaginally as an outpatient and can ameliorate abdominal discomfort and relieve respiratory distress. Re-accumulation of ascites may prompt additional paracenteses or rarely, placement of a percutaneous pigtail catheter. Untreated hypovolemia can lead to renal, hepatic, or pulmonary end-organ failure. Thus, fluid balance must be maintained by replacement with an isotonic fluid such as normal saline. Monitoring of electrolytes is critical. Because of hypercoagulability in these women, prophylaxis for thromboembolism should strongly be considered with severe OHSS (see Table 39-11).

Prevention

Strategies to avoid OHSS during exogenous ovulation induction include decreasing follicular stimulation (a decreased FSH dose), "coasting" (withholding FSH administration for one or more days prior to hCG injection), substitution of hCG for FSH during the final days of ovarian stimulation, and prophylactic treatment with volume expanders.

If concern of OHSS is present during induction, then the hCG trigger can be withheld, resulting in cycle cancellation. Alternatively, a single dose of a GnRH agonist such as leuprolide acetate (Lupron, TAP Pharmaceutical, Lake Forest, IL) can be used in place of hCG. This results in an endogenous LH surge, which can bring about the final stages of follicle and oocyte maturation without significant risk of OHSS. Prevention of pregnancy does not completely eliminate the risk of OHSS, but certainly serves to limit the duration of the symptoms. Thus, an additional option in ART cycles is to freeze all embryos and forgo embryo transfer that cycle.

Multifetal Gestation

Higher-order multifetal pregnancy is an adverse outcome of infertility treatment, and in general, increased fetal numbers lead to greater risk of perinatal and from maternal morbidity and mortality. In these cases, prematurity leads to most adverse events, but fetal growth restriction and discordance may also be factors.

From 1980 through 1997, the number of twin births rose by slightly more than 50 percent, whereas the number of higher-order multifetal births increased by over 400 percent (Fig. 20-6) (Martin, 1999). In an analysis of recent data from the Society for Assisted Reproductive Technology (SART) and from the Centers for Disease Control and Prevention (CDC) National Center for Health Statistics (2000), the CDC has estimated that approximately 20 percent of triplets and higher-order multifetal births were attributable to spontaneous events; 40 percent were related to ovulation-inducing drugs without ART; and 40 percent resulted from ART. However, further analysis of the same data indicates that the overwhelming majority of all multifetal births results from spontaneously conceived twin gestations and that only approximately 10 percent result from IVF and related procedures.

Trends in frequency of multifetal gestation deliveries. **A.** Number of twin births in the United States from 1980 to 1997. **B.** Number of triplet and higher-order multifetal births in the U.S. for the same time period. *(From Martin, 1999, with permission.)*

That said, several issues in infertility care contribute to the increased incidence of higher-order multifetal pregnancies. An infertile couple's sense of urgency may lead to a preference for more aggressive strategies involving gonadotropin treatment or for more embryos to be transferred in IVF cycles. Clinicians may feel competitive pressures to achieve higher pregnancy rates and may be inclined to turn to superovulation (SO) or IVF earlier in treatment or to transfer a greater number of embryos.

Efforts to reduce multifetal gestation using serum estradiol limits and arbitrary sonographic criteria of follicular size in patients undergoing ovulation induction (OI) or SO have been ineffective (Gleicher, 2000). In a multicenter randomized clinical trial involving 1,255 OI cycles, hCG was withheld if the estradiol concentration rose above 3,000 pg/mL or more than six follicles greater than 18 millimeters in diameter were present (Guzick, 1999). Despite these limits on hCG administration, the multifetal gestation rate was still 30 percent. Although sonography and serum estradiol monitoring have not reduced the incidence of multifetal gestation and OHSS, the risk of multifetal pregnancy does correlate with the magnitude of follicular response as indicated by follicle number and serum estradiol levels. However, there is no consensus among centers regarding specific sonographic criteria or estradiol levels beyond which hCG should not be administered.

Patients with higher-order multifetal gestations are faced with options of continuing their pregnancy, with all the risks previously described; terminating the entire pregnancy; or electing multifetal pregnancy; reduction (MFPR). Reduction lowers the number of

fetuses to decrease the risk of maternal and perinatal morbidity and mortality. Although MFPR decreases risks associated with preterm delivery, it often creates profound ethical dilemmas. Moreover, multifetal reduction reduces, but does not eliminate, the risk of fetal growth restriction in remaining fetuses. With MFPR, pregnancy loss and prematurity are primary risks. However, current data suggest that such complications have decreased as experience with the procedure has grown (Evans, 2005).

OVARIAN DRILLING

Surgical ovarian wedge resection was the first established treatment for anovulatory PCOS patients. It was largely abandoned because of postsurgical adhesion formation, which converted endocrinologic subfertility to mechanical subfertility (Adashi, 1981; Buttram, 1975; Stein, 1939). As a result, it was replaced by medical ovulation induction with CC and gonadotropins (Franks, 1985). However, medical ovulation induction, as discussed earlier, has limitations. Accordingly, surgical therapy using laparoscopic techniques known as laparoscopic ovarian drilling (LOD) is an alternative in women resistant to medical therapies.

During LOD, electrosurgical coagulation, laser vaporization, or harmonic scalpel may be used to create multiple perforations in the ovarian surface and stroma (see Section 41-32, Ovarian Drilling). In many uncontrolled observational studies, drilling has led to a temporary high rate of spontaneous postoperative ovulation and conception, or to improved medical ovulation induction (Armar, 1990, Farhi, 1995; Greenblatt, 1987; Kovacs, 1991).

The mechanism of action with LOD is thought to be similar to that of ovarian wedge resection. Both procedures may destroy ovarian androgen-producing tissue and reduce peripheral conversion of androgens to estrogens. Specifically, a fall in serum levels of androgens and LH, and an increase in FSH levels have been demonstrated after ovarian drilling (Armar, 1990; Greenblatt, 1987). The endocrine changes following surgery are thought to convert the adverse androgen-dominant intrafollicular environment to an estrogenic one, and to restore the hormonal environment to normal by correcting disturbances of ovarian-pituitary feedback (see Chap. 17, Insulin Resistance). (Aakvaag, 1985; Balen, 1993). Thus, both local and systemic effects are thought to promote follicular recruitment and maturation and subsequent ovulation.

Risks of ovarian drilling include postoperative adhesion formation as well as the other risks of laparoscopic surgery (see Section 41-28, Laparoscopy). Additionally, theoretical risks of diminished ovarian reserve and premature ovarian failure remain to be well investigated. As surgery is more invasive, ovarian drilling is generally not offered prior to consideration of medical therapies.

Correction of Diminished Ovarian Reserve

Ovarian dysfunction may result from ovarian failure or from a diminished ovarian reserve, either of which may follow normal aging, disease, or surgical castration. Even if a woman is spontaneously menstruating, a basal (day 2 or 3) FSH level above 15 IU/L predicts that medical therapies including exogenous gonadotropins will be of little benefit. For these women, the option of using donor eggs should be considered. Expectant management may also be considered, although the likelihood of pregnancy is low.

Correction of Anatomic Abnormalities

Anatomic distortions of the female reproductive tract are a major cause of infertility and may prevent ovum entry into the fallopian tube; impair transport of ova, sperm, or embryos; or interfere with implantation. The three primary types of anatomic abnormalities include tubal factors, peritoneal factors, and uterine factors. Each has differing effects and therefore may require different therapies.

TUBAL FACTORS

Tubal occlusion can arise from congenital abnormality, infection, or iatrogenic causes (see Chap. 18, Fallopian Tube Anomalies). Additionally, a small subset of tubal infertility is idiopathic. Not only the cause of tubal damage, but also the nature of an anatomic abnormality is important. For example, proximal tubal occlusion, distal tubal occlusion, and tubal absence differ markedly in their treatment.

Proximal tubal occlusion describes obstruction proximal to the fimbria and may develop at the tubal ostium, isthmus, or ampulla. Specifically, *midtubal occlusion* is considered a subset of proximal occlusion. Proximal tubal occlusion may be secondary to tubal resection, luminal obliteration, or simply plugging with mucus or debris. In contrast, *distal tubal occlusion* describes obstruction at the tube's fimbria. It typically results from prior pelvic infection and may be associated with concomitant adnexal adhesions.

Tubal Cannulation

Proximal tubal occlusion is often amenable to direct techniques. If diagnosed at the time of hysterosalpingography (HSG), consideration should be given to performing concurrent selective salpingography (see Chap. 2, Selective Salpingography). A catheter is placed such that it wedges within the tubal ostium. This allows significantly greater hydrostatic pressure to be applied to the tube. Such pressure will likely overcome most instances of tubal spasm or plugging by mucus or debris. If patency of the tube cannot be established, an inner catheter with guidewire is used to cannulate the tube. This creates patency of isolated short segmental scarring in most instances. Scarring of a longer segment or luminal obliteration, however, is not amenable to correction with tubal cannulation. In these women, surgical segmental resection and reanastomosis or IVF may be considered.

TUBAL RECONSTRUCTION

Proximal Tubal Obstruction

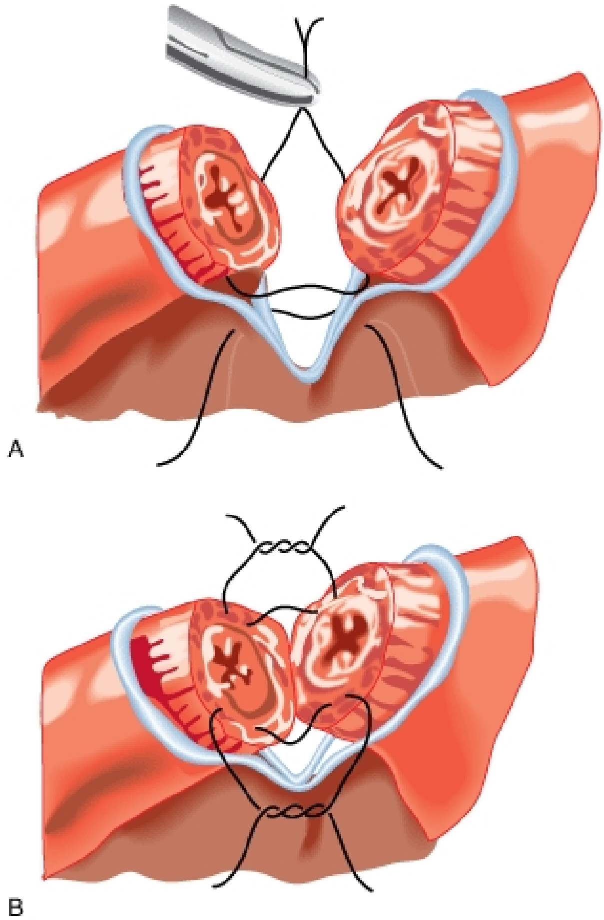
Tubal obstruction not amenable to treatment with selective salpingography has traditionally been treated surgically, and options include hysteroscopic cannulation, surgical reanastomosis, and neosalpingostomy. Although there have been considerable increases in the success rates of ART, reproductive surgery remains an important option or complement to ART for many couples.

Some types of tubal blockage have a much better prognosis with surgical therapy than others. For example, hysteroscopic cannulation of fallopian tubes can treat some types of proximal obstruction in a fashion similar to selective salpingography (see Section 41-40, Hysteroscopic Proximal Fallopian Tube Cannulation). Hysteroscopic cannulation is best performed with concurrent laparoscopy to verify distal tubal patency.

Proximal obstruction not amenable to cannulation techniques can be treated with segmental resection and reanastomosis. In most cases, this can be done as an outpatient procedure through a mini-laparotomy incision. However, obstruction extending into the interstitial portion of the tube is more technically challenging to repair and more prone to obstruction postoperatively. Therefore, proximal occlusion extending to the interstitial segment that cannot be treated with cannulation is best treated in most instances with IVF.

Proximal and midtubal occlusion resulting from prior sterilization can be treated with either tubal reanastomosis or IVF (Fig. 20-7). From a patient perspective, outpatient tubal reanastomosis avoids ovarian stimulation and increased risk for multifetal gestation and provides an ability to conceive normally. In general, although the monthly probability of pregnancy following tubal reversal is likely lower than age-matched controls without prior sterilization, the cumulative chance of pregnancy is high. However, IVF should be strongly considered if other fertility factors are present or the type of sterilization performed does not permit reconstruction. For example, in cases of sterilization completed by fimbriectomy, neosalpingostomy can be corrective, however, the probability of pregnancy is lower and IVF should be considered.

FIGURE 20-7



Surgical reanastomosis of fallopian tube segments. The scarred portion of the tube is sharply excised until nonfibrotic tubal tissues are reached. **A.** The mesosalpinx is re-approximated with interrupted stitches using 6-0 delayed-absorbable suture. **B.** The tubal muscularis is re-approximated with single stitches in each quadrant using 7-0 delayed-absorbable suture. Tubal serosa is closed with interrupted or running 6-0 delayed-absorbable suture.

The reversibility of sterilization can generally be determined by review of the operative report and pathology report if the procedure involved segmental resection. If operative records are unavailable or suggest that reanastomosis may not be feasible, laparoscopy is performed prior to laparotomy to assess chances of surgical success.

Outpatient reversal of sterilization is most commonly done by mini-laparotomy. Incision size typically varies from 3 to 6 cm, depending on a patient's weight and anatomy. Some surgeons are able to complete some of these procedures by laparoscopy. Robotic control may be helpful for this, but may increase operating time and expense.

Distal Tubal Obstruction

Following pelvic inflammatory disorders, normal fimbrial anatomy may be destroyed or fimbria may be encased by concomitant adnexal adhesions. In these cases, neosalpingostomy can be performed at mini-laparotomy or laparoscopy (Fig. 20-8). However, women desiring neosalpingostomy for treatment of distal occlusion should be counseled that the risk of ectopic pregnancy is high, the likelihood of pregnancy is 50 percent or lower, and postoperative re-occlusion is common (Bayrak, 2006). Moreover, hydrosalpinges that are dilated more than 3 cm in diameter, that are associated with significant adnexal adhesions, or that display an obviously attenuated endosalpinx yield a poor prognosis. These tubes are best treated by salpingectomy and plans for IVF. If both tubes are affected, bilateral salpingectomy is recommended prior to proceeding with IVF to improve IVF pregnancy rates

(Practice Committee of the American Society of Reproductive Medicine, 2004b).

Neosalpingostomy. **A.** The distal end of the clubbed fallopian tube is opened sharply or with electric or laser energy. **B.** The endosalpinx is everted using Cuff or Bruhat technique.

CORRECTION OF UTERINE FACTORS

Three types of uterine factors have been implicated in infertility and include leiomyomas, endometrial polyps, and intrauterine adhesions. Mechanisms of infertility with these factors have not been clearly elucidated, however, the end result is decreased endometrial receptivity and reduced likelihood of embryo implantation.

Leiomyomas

Leiomyomas are common benign tumors of the uterus and have been associated with infertility in some women. Retrospective studies have suggested a benefit from surgically removing these tumors to increase efficacy of both natural and assisted conception (Griffiths, 2006).

There are no randomized controlled trials to clearly demonstrate that myomectomy improves fertility. However, in view of the many retrospective observational studies that suggest this, it is reasonable to offer myomectomy to infertile women, especially if tumors are large or impinge on the endometrial cavity. Myomectomy can be performed using hysteroscopy, laparoscopy, or via laparotomy, and selection of the approach is discussed in Chapter 9, Surgical Management. Currently, no studies validate one method compared with another in terms of efficacy. Therefore, clinical judgment should determine the most appropriate technique from the standpoint of safety, restoration of normal uterine anatomy, and speed of recovery.

Endometrial Polyps

These soft fleshy endometrial growths are commonly diagnosed during evaluation of infertility. Several studies have suggested good pregnancy rates following polypectomy, although the mechanism by which polyps may impair fertility has not been established. The requirement to remove even small polyps in infertile women has been previously debated. However, a recent prospective trial of 204 women with polyps and with an additionally diagnosed cervical factor, male factor, or unexplained infertility

appears to give some clear guidance with regard to this issue.

In this trial, women were randomized to one of two groups prior to treatment with intrauterine insemination (IUI) (PÃ©rez-Medina, 2005). The first group underwent polypectomy. The second underwent only hysteroscopic biopsy of the polyp to obtain histologic confirmation. All patients were managed expectantly for three cycles prior to proceeding with up to four cycles of IUI. The pregnancy rate in the polypectomy group was more than twice as high regardless of polyp size (Table 20-6). These data suggest that endometrial polyps can significantly impair outcome of infertility treatment. Thus, it would seem prudent to perform hysteroscopic polypectomy in all infertile women if a polyp is identified (Section 41-38, Polypectomy).

Table 20-6 Number and Percentage of Pregnancies after Hysteroscopic Polypectomy (*n* = 204)

	Polypectomy *n = 101 (%)*	**Control *n = 103 (%)***	***p-value***

Intrauterine Adhesions

Adhesions within the endometrial cavity, also called *synechiae,* can range from asymptomatic small bands to complete or near complete obliteration of the endometrial cavity. If amenorrhea or hypomenorrhea result, the condition is termed *Asherman syndrome* (see Chap. 18, Asherman Syndrome).

Treatment involves surgical adhesiolysis to restore normal uterine cavity size and configuration. Dilatation and curettage (D&C) and abdominal approaches have previously been used. However, with the advantages of hysteroscopy, the role of these techniques has been minimized (see Section 41-41, Lysis of Intrauterine Adhesions).

Hysteroscopic adhesion resection may range from simple lysis of a small band to extensive adhesiolysis of dense intrauterine adhesions using scissors, electrosurgical cutting, or laser energy. However, women in whom the uterine fundus is completely obscured and those with a markedly narrowed, fibrotic cavity present the greatest therapeutic challenge. Several techniques have been described for these difficult cases, but outcome is far worse than in patients with small band adhesions. In women with severe Asherman syndrome that is not amenable to reconstructive surgery, gestational carrier surrogacy is a valuable option.

TREATMENT OF PERITONEAL DISEASE

Endometriosis and pelvic adhesions are two types of peritoneal disease that frequently contribute to infertility and that may develop independently or concurrently.

Endometriosis

This condition and its effects on infertility are extensively discussed in Chapter 10, Infertility. In women with minimal or mild disease, evidence supporting lesion ablation is limited, and use of empiric general fertility boosting procedures such as ART or superovulation combined with IUI is reasonable. These treatments have been validated to increase fecundity in women with stage I and II disease (Table 20-7) (Guzick, 1999).

Table 20-7 Cycle Fecundity in Women with Stage I or II Endometriosis, According to Treatment

From American Society of Reproductive Medicine, 2004a, with permission.

Moderate and severe endometriosis results in distortion of anatomic relationships of reproductive organs. In many cases, surgical treatment may improve anatomy and pregnancy may result (Practice Committee of the American Society of Reproductive Medicine, 2004a). Unfortunately, advanced disease may prevent adequate restoration of pelvic anatomy. Therefore, a surgeon's operative findings and anticipated surgical results should guide postoperative strategy. If a satisfactory surgical outcome is achieved, it is reasonable to attempt pregnancy for 6 to 12 months prior to considering other options such as IVF. It should be remembered that endometriosis in some cases may recur quickly, and unnecessary delay in attempting pregnancy postoperatively is not advised.

Several studies suggest that in women with advanced endometriosis, long-term treatment with a GnRH analog before initiation of a cycle may improve fecundity (Dicker, 1992; Surrey, 2002). At the present time, however, this treatment strategy is not universally accepted.

If endometriomas are noted, a surgeon may select: cyst drainage, drainage followed by cyst wall ablation, or cyst excision. All three procedures can be performed laparoscopically in nearly all circumstances given adequate surgeon experience. Simple drainage minimizes ovarian destruction, but most commonly results in rapid cyst recurrence. A recent study demonstrated that a mean of 60 percent of the cyst wall (range of 10 to 98 percent) was lined by endometrium to a depth of 0.6 mm (Muzii, 2007). Therefore, drainage and ablation is also associated with significant risk of cyst recurrence as well as thermal damage to the ovary. For these reasons, laparoscopic excision of the cyst wall by a stripping technique should be considered optimal treatment for most endometriomas (see Section 41-33, Laparoscopic Ovarian Cystectomy). However, excision is inevitably accompanied by removal of normal ovarian tissue in more than 80 percent of cases and often leads to decreased ovarian volume and diminished ovarian reserve.

Adhesions

Pelvic adhesions may result from endometriosis, prior surgery, or pelvic infection and often vary in their density and vascularity. Adhesions may impair fertility by distorting adnexal anatomy and interfering with gamete and embryo transport even in the absence of tubal disease.

Surgical lysis may restore pelvic anatomy in some cases, but adhesions may recur, especially if dense and vascular. Adherence to

microsurgical principles and minimally invasive surgery may help decrease adhesion formation. Although numerous adjuvants have been used to reduce the risk of postoperative adhesion formation, currently none have been validated to improve fecundity (Practice Committee of the American Society of Reproductive Medicine, 2006).

Among infertile women with adnexal adhesions, pregnancy rates after adhesiolysis are 32 percent and 45 percent at 12 and 24 months of surveillance, respectively, compared with 11 percent (at 12 months) and 16 percent (at 24 months) in those left untreated (Tulandi, 1990). As with severe endometriosis, clinical judgement regarding operative findings and results of surgery should guide the strategy postoperatively. In vitro fertilization is the best option for those with a poor prognosis for restoration of normal anatomy.

Correction of Cervical Abnormalities

In response to follicular estradiol production, the cervix should produce abundant thin mucus. If present, this mucus acts as a conduit and functional reservoir for sperm (see Fig. 19-9). Accordingly, inadequate cervical mucus impairs sperm transport to the upper female reproductive tract.

Causes of abnormal or deficient mucus include infection, prior cervical surgery, use of anti-estrogens (e.g., clomiphene citrate) for ovulation induction, and sperm antibodies. However, many women with decreased or hostile mucus have no history of predisposing factors.

Examination of cervical mucus may reveal gross evidence of chronic cervicitis that deserves treatment. Alternatively, in those with decreased mucus volume, treatments include short-term supplementation with exogenous estrogen such as ethinyl estradiol and the use of the mucolytic expectorant, guaifenesin. However, the value of estrogen and guaifenesin has not been confirmed. Moreover, exogenous estrogens could have a negative effect on follicular development and ovarian function.

For these reason, most clinicians treat noninfectious, suspected cervical mucus abnormalities with IUI. Although this treatment also has not been validated in randomized prospective trials (Helmerhorst, 2005), the theoretical basis for this approach seems sound. Additionally, IUI has been demonstrated to be effective for treatment of unexplained infertility. As a result, many clinicians forgo cervical mucus testing and proceed directly with IUI treatments in the absence of tubal disease (Fig. 20-9).

FIGURE 20-9

Intrauterine insemination (IUI). Prior to IUI, partner or donor sperm is washed and concentrated. Signs of impending ovulation are monitored with transvaginal sonography. At the time of suspected ovulation, a long, thin catheter is threaded through the cervical os and into the endometrial cavity. A syringe containing the sperm concentrate is attached to the catheter's distal end, and the sperm sample is injected into the endometrial cavity.

Correction of Male Infertility

Male infertility has varied causes and may include abnormalities of semen volume such as aspermia and hypospermia or of sperm number such as azoospermia and oligospermia. Additionally, motility may be limited, termed asthenospermia, or sperm structure may be abnormal, teratozoospermia. Accordingly, therapy should be planned only after thorough evaluation (see Chap. 19, Normal Spermatogenesis).

In the absence of an identifiable correctable cause for semen or sperm abnormalities, it is appropriate to offer IUI or ART as treatment options. The choice of whether to proceed initially with IUI as opposed to the more intensive and expensive ART treatments is dependent on several factors. These include duration of infertility, age of the female, and history of prior treatments. If ART is considered for male factors, intracytoplasmic sperm injection (ICSI) (Fig. 20-10) is typically selected rather than traditional IVF.

ASPERMIA

This condition is characterized by a complete lack of semen and results from failure to ejaculate. The physiology of ejaculation includes emission of sperm with accessory gland fluid into the urethra, simultaneous closure of the urethral sphincters, and forceful ejaculation of semen through the urethra. Emission and closure of the bladder neck are primarily α-adrenergically mediated thoracolumbar sympathetic reflex events with supraspinal modulation. Ejaculation is a sacralspinal reflex mediated by the pudendal nerve.

Anejaculation or anorgasmia is not a rare complaint and may be related to psychogenic factors, organic erectile dysfunction, or impaired parasympathetic sacralspinal reflex. Appropriate treatments depend on the cause and may include psychological counseling or erectile dysfunction treatment with sildenafil citrate (Viagra, Pfizer, New York, NY) or other similar medication. Vibratory stimulation may also be effective in some instances. Electroejaculation is an invasive procedure and is generally used for men with spinal cord injuries that are unresponsive to the therapies above.

Men who achieve orgasm but never experience prograde ejaculation or have a greatly reduced prograde volume typically have retrograde ejaculation. Therefore, administration of oral pseudoephedrine or other α-adrenergic agent to aid bladder neck closure is warranted. However, for many, pharmacologic methods are ineffective, and IUI may be performed using sperm processed from a voided postejaculatory urine specimen.

A minority of men who achieve orgasm, but not prograde ejaculation, have failure of emission. Treatment with sympathomimetic agents may be attempted in these individuals as well, although pharmacologic therapies have generally met with limited success. Alternatively, testicular or epididymal extraction of sperm via aspiration or biopsy may be used in cases refractory to medication. As with electroejaculation, this technique recovers a limited number of viable sperm and is best suited for use with ICSI.

HYPOSPERMIA

Hypospermia or low semen volume (less than 2 mL) impairs transport of sperm into cervical mucus and may be associated with decreased sperm density or motility. Retrograde ejaculation may underlie this condition and treatment follows that described for aspermia.

Alternatively, hypospermia may follow partial or complete ejaculatory duct obstruction. In these cases, transurethral resection of ejaculatory ducts has resulted in marked improvement in semen parameters, and pregnancies have been achieved. However, couples should be counseled that postoperative complete obstruction of the ejaculatory ducts is not rare. Thus, consideration should be given to cryopreservation of sperm prior to surgical attempts in those individuals with partial obstruction.

AZOOSPERMIA

Characterized by the total absence of sperm in semen, azoospermia may result from obstruction in the male reproductive tract or from nonobstructive causes.

Obstructive azoospermia, especially resulting from prior vasectomy or ejaculatory duct obstruction, may be amenable to surgical treatment. However, congenital bilateral absence of the vas deferens (CBAVD) is a common cause of azoospermia, and is unfortunately not treatable surgically. In such candidates, testicular sperm extraction (TESE) may be performed in conjunction with ICSI.

Nonobstructive azoospermia may be caused by a karyotypic abnormality such as Klinefelter syndrome (47,XXY) or balanced translocation, deletion of a small portion of the Y chromosome, testicular failure, or by unexplained causes. In many cases, TESE may be combined effectively with ICSI in those with Klinefelter syndrome and Y microdeletion of the AZFc region. However, in men with Y microdeletion in the AZFa or AZFb region, this ART combination has been ineffective (Choi, 2004).

OLIGOSPERMIA

Oligospermia is diagnosed if fewer than 20 million sperm are present per milliliter of semen. Causes are varied and include hormonal, genetic, environmental (including medications), and unexplained causes. Additionally, an obstructive cause, especially ejaculatory duct obstruction, should be considered if oligospermia is seen in conjunction with low semen volume. If severe oligospermia (<5 to 10 million sperm per mL) is noted, then an evaluation similar to that for azoospermia is warranted.

Oligospermia in the absence of decreased sperm motility not uncommonly reflects hypogonadotropic hypogonadism. In general, hypogonadotropic hypogonadism is best treated with injections of FSH and hCG. Alternatively, clomiphene citrate and aromatase inhibitors, although not FDA-approved treatment for this indication, may be considered in some instances, especially if obesity and elevated serum estradiol levels are present. Spermatogenesis is a long process lasting approximately 100 days, and several months may be required to identify significant improvements in sperm density with either treatment.

Environmental factors such as excessive exposure to high temperatures should be investigated. Drug and medication history should also be obtained. If an environmental factor is identified, correction may improve sperm numbers.

ASTHENOSPERMIA

Asthenospermia or decreased sperm motility may be seen alone or in combination with oligospermia or other abnormal semen parameters. In general, asthenospermia does not respond to directed treatments. Expectant management may be considered, especially if the duration of infertility is short, and maternal age is less than 35 years. For treatment, IUI and ICSI are preferred, although IUI is generally not successful in severe cases (Centola, 1997). If fewer than one million motile sperm are available for insemination following semen processing, or the couple has experienced more than 5 years of infertility, then ICSI should be considered as initial therapy (Ludwig, 2005a).

TERATOZOOSPERMIA

Teratozoospermia, that is, abnormal sperm morphology is most often seen in conjunction with oligospermia, asthenospermia, and oligoasthenospermia. Directed treatments for teratozoospermia are not available and therapy options include IUI and ART. Because teratozoospermia may commonly be accompanied by sperm function defects that may impair fertilization, ICSI should be considered if ART is selected.

VARICOCELE

This dilation of the blood vessels in the scrotum is usually left-sided and results from dilatation of the pampiniform plexus of the spermatic vein (see Fig. 19-3). Traditional treatment is surgical ligation of the internal spermatic vein. With ligation, several surgical techniques have been employed, but retroperitoneal high ligation or transinguinal ligation is the most frequently performed. More recently, interventional radiographic techniques that selectively catheterize and embolize the internal spermatic vein with sclerosing solutions, tissue adhesives, or detachable balloons or coils have been used as alternatives. Despite the widespread application of varicocele treatments, there is insufficient evidence to conclude that treatment of a clinical varicocele in couples with male subfertility improves the likelihood of conception (see Chap. 19, The Male History) (Evers, 2003).

UNEXPLAINED INFERTILITY

Unexplained infertility may represent one of the most common infertility diagnoses, with a reported prevalence of up to 30 percent (Dodson, 1987). The diagnosis of unexplained infertility is highly subjective and depends on the diagnostic tests performed or omitted and on their level of quality. Paradoxically, a diagnosis of unexplained infertility, therefore, will be more often reached if the evaluation is incomplete or of poor quality (Gleicher, 2006). Nevertheless, a diagnosis of unexplained infertility can, by definition, not be directly treated. Expectant management may be considered, especially with infertility of short duration and with relatively young maternal age. However, if treatment is desired, then IUI, superovulation, and ART are empiric appropriate interventions to consider.

INTRAUTERINE INSEMINATION

This technique processes semen and separates motile, morphologically normal spermatozoa from dead sperm, leukocytes, and seminal plasma. This highly motile fraction is then inserted transcervically via a flexible catheter near the anticipated time of ovulation (Fig. 20-9). Intrauterine insemination can be performed with or without superovulation (SO) and is appropriate therapy for treatment of cervical factors, mild and moderate male factors, and unexplained infertility.

If performed for cervical factors, IUI timed by urine LH surge is an initial strategy that achieves reasonable pregnancy rates of up to 11 percent per cycle (Steures, 2004). Although this rate is lower than that seen with SO combined with IUI, SO side effects and costs are avoided.

In contrast, for unexplained infertility and for male factors, IUI is most commonly performed in conjunction with SO. A combination of clomiphene citrate and IUI was evaluated by Deaton and colleagues (1990) in a randomized trial. In this study, the treatment group had a significantly higher pregnancy rate (9.5 percent) compared with controls (3.3 percent). Gonadotropin treatment (FSH or hMG) alone has been shown to increase the likelihood of pregnancy, but the benefit is markedly improved with the addition of IUI.

ASSISTED REPRODUCTIVE TECHNOLOGIES

Assisted reproductive technologies describes clinical and laboratory techniques used to achieve pregnancy in infertile couples for whom direct corrections of underlying causes are not feasible. In principle, IUI meets this definition. By convention, however, ART procedures are those that at some point require extraction and isolation of an oocyte. These techniques include, but are not limited to, in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), egg donation, gestational carrier surrogacy, gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT). Additional ART-associated techniques include egg and embryo cryopreservation, testicular sperm extraction (TESE), in vitro maturation of oocytes (IVM), and pre-implantation genetic diagnosis (PGD).

In Vitro Fertilization

During IVF, mature oocytes from stimulated ovaries are retrieved transvaginally with sonographic guidance (Figs. 20-11 and 20-12). Sperm and ova are then combined in vitro to prompt fertilization (Fig. 20-13). If successful, viable embryos are transferred transcervically into the endometrial cavity using sonographic guidance (Fig. 20-14).

FIGURE 20-11

In vitro fertilization (IVF). Superovulation is induced with one of the protocols displayed in Figures 20-2 and 20-3, and follicle maturation is monitored over several days sonographically. Near ovulation, a transvaginal approach is used to harvest eggs from the ovaries. These oocytes are fertilized in vitro and fertilized eggs develop to the blastocyst stage. Blastocysts are then drawn up into a syringe and delivered into the endometrial cavity.

FIGURE 20-12

Embryo transfer performed using abdominal sonographic guidance for proper placement. Catheter (arrow) is seen within the endometrial cavity.

Similarly to IUI, substantial benefit is achieved using controlled ovarian hyperstimulation (COH) prior to egg retrieval. Many ova are genetically or functionally abnormal, and thus exposure of several ova to sperm results in an increased chance of a healthy embryo.

Most often, GnRH analogs are used in conjunction with gonadotropins (FSH or hMG) to prevent the possibility of spontaneous LH surge and ovulation prior to egg retrieval. Optimally, 10 to 20 ova are harvested, and from these, ideally one healthy embryo is transferred.

Unfortunately, methods to determine embryo health are imperfect. Therefore, to maximize the probability of pregnancy, more than one embryo is typically transferred, thus resulting in increased risk of multifetal gestation. More recently, advances in culture conditions permit embryos to be cultured to the blastocyst stage, which allows transfer of fewer embryos, yet maintains high pregnancy rates (Langley, 2001).

As discussed in Chapter 9, Hydrosalpinx, hydrosalpinges should be removed or tubal interruption performed prior to proceeding with IVF to increase implantation rates and decrease the risk of miscarriage.

Intracytoplasmic Sperm Injection

This variation on IVF is most applicable to male factor infertility. During the micromanipulation technique of ICSI, cumulus cells surrounding the ova are enzymatically digested, and a single sperm is directly injected through the zona pellucida and oocyte cell membrane (Fig. 20-10). Pregnancy rates with ICSI are comparable with those achieved with IVF for other causes of infertility.

For azoospermic men, ICSI has made pregnancy possible. In these cases, sperm are mechanically extracted from the testicle or epididymis.

Gestational Carrier Surrogacy

This variation on IVF places a fertilized egg into the uterus of a surrogate, rather than into the intended mother. Indications are varied, and this approach may be appropriate for women with uncorrectable uterine factors, for those in whom pregnancy would pose significant health risks, and for those with repetitive unexplained miscarriage.

Gestational carrier surrogacy has legal and psychosocial issues. In most states, a surrogate is the legal parent, and therefore adoption must be completed after birth to give the intended mother her parental rights. However, a few states have adopted specific laws that extend protection to the intended parents.

Egg Donation

Egg donation may be employed in cases of infertility associated with ovarian failure or diminished ovarian reserve. Additionally, this technique may also be used to achieve pregnancy in fertile women when offspring would be at risk for maternally transmitted genetic disease. Egg donors may be known to the recipient couple, or more commonly are anonymous young women recruited by an agency or IVF center.

At present, the highest success rates require the use of "fresh" or noncryopreserved oocytes. For this reason, an egg donation cycle requires synchronization of a recipient's endometrium with egg development of the donor. Commonly, if a recipient is not menopausal, GnRH agonists are used to suppress gonadotropin production and allow for a controlled artificial cycle. Following suppression, exogenous estrogen is given beginning just prior to the start of gonadotropin administration to an egg donor. After a donor receives hCG to allow the final stages of follicle and egg maturation, the recipient begins progesterone. In the recipient, estrogen and progesterone are typically continued until late in the first trimester when placental production of these hormones is deemed to be adequate.

Gamete Intrafallopian Transfer

This technique is similar to IVF in that egg retrieval is performed after COH. Unlike IVF, however, fertilization and early embryo development does not take place in the laboratory. Eggs and sperm are placed via catheter through the fimbria and deposited directly into the oviduct. This transfer of gametes is most commonly performed at laparoscopy. Like IUI, GIFT is most applicable for unexplained infertility and should not be considered for tubal factor causes of infertility.

This technique was most popular in the late 1980s and early 1990s. However, as laboratory techniques have improved, IVF has largely replaced GIFT. In general, GIFT is more invasive, provides less diagnostic information, and requires transfer of more than two eggs for optimal pregnancy chances, which increases the risk of higher-order multifetal gestation. Thus, the major indication for GIFT at present is to avoid the religious or ethical concerns that some patients may have with fertilization taking place outside the body.

Zygote Intrafallopian Transfer

This technique is a variant of IVF with similarities to GIFT. Embryo transfer is not performed directly into the uterine cavity, but rather into the fallopian tube at laparoscopy. If the transfer is completed after an embryo has begun to divide, the procedure is more accurately termed *tubal embryo transfer* (TET). Although a normal fallopian tube may provide a superior environment for the early-stage embryo, this advantage has been lessened with improvements in laboratory culture methods. Accordingly, ZIFT currently should be considered most appropriately in the rare case in which transcervical transfer during IVF is technically not feasible.

Embryo Cryopreservation

With IVF, many eggs are retrieved to have ultimately one to three healthy embryos for transfer. This frequently leads to extra embryos. Successful freezing and thawing of embryos has been possible for two decades. Advances in cryoprotectants and techniques have allowed improved survival rates of embryos frozen at a variety of developmental stages. With cryopreservation, these supernumary embryos can yield pregnancies later, obviating the need for ovarian stimulation and egg retrieval.

Oocyte Cryopreservation

Significant technical challenges have been encountered with cryopreservation of unfertilized eggs. At this time, oocyte

cryopreservation is still considered by most to be experimental and long-term outcomes are unknown. This technique, however, is proving useful in attempting to preserve the fertility potential of women facing gonadotoxic chemotherapy (Marhhom, 2007). As success improves, oocyte cryopreservation may assist women desiring to delay childbearing and will likely lead to expansion of egg donation programs.

In Vitro Maturation

This technique has been used to achieve pregnancy by aspirating antral follicles from unstimulated ovaries and culturing these immature oocytes to allow resumption and completion of meiosis in vitro. Currently, IVM is considered experimental and long-term outcomes are unknown. This technique may be useful in patients with PCOS in whom stimulation poses a significant risk of OHSS. Additionally, it is possible that refinement and evolution of this technique may make possible maturation of ova from pre-antral follicles. This could potentially allow preservation of fertility potential for women in whom gonadotoxic chemotherapy is required.

Pre-Implantation Genetic Diagnosis

This laboratory technique removes cells from a developing embryo for screening of genetic disease. Typically performed by removing one or two cells at the six- to eight-cell stage, this technique can screen for single gene defects, unbalanced translocations, and aneuploidy (Fig. 20-15). Pre-implantation genetic diagnosis is considered an experimental procedure at this time, and implementation of newly developed methods for genetic analysis will likely continue to broaden its application.

Complications of Assisted Reproductive Technologies

Assisted reproductive technologies in most cases lead to successful delivery of healthy singleton pregnancies. However, there are complications of pregnancy that may develop more frequently in those conceived using ART. Of these, risk of multifetal gestation is the most common. However, risks of prematurity or fetal growth restriction that is independent of maternal age and fetal number are also increased. In addition, increased rates of major congenital defects, epigenetic abnormalities, and placenta previa have been noted in IVF-conceived pregnancies (Ludwig, 2005b; Olson, 2005). Accordingly, in view of the above increased risks, it is reasonable to consider more intensive prenatal assessment in pregnancies conceived by IVF.

Fortunately, currently available data suggest that there are no differences between the psychomotor development of preschool children conceived by IVF and naturally conceived children. Similarly, the socio-emotional development of children conceived by IVF in this age group appears comparable with that of naturally conceived children (Ludwig, 2006).

CONCLUSION

The treatment of infertility should be initiated only after a thorough investigation as outlined in the Chapter 19. The initial focus should be to identify lifestyle or environmental issues that may contribute to or cause reproductive impairment. Obesity, adequate nutrition, and associated stress should not be overlooked. In general, it is desirable to correct any identifiable contributors to subfertility. In many cases, no obvious cause can be detected. In other couples, a cause may be identifiable, but not amenable to directed corrective therapies. In these circumstances, generalized fertility-boosting strategies may be recommended. These treatments include intrauterine insemination (with or without superovulation) and assisted reproductive technologies (ART).

It is important to recognize that superovulation and ART are not without risks and couples should be appropriately counseled. Additionally, these techniques may involve third parties (egg, sperm, or embryo donors or gestational carriers). These procedures are associated with unique psychosocial, legal, and ethical considerations. Emerging technologies such as preimplantation genetic testing bring additional ethical issues that must be confronted and resolved by both patient and practitioner.

MENOPAUSAL TRANSITION: INTRODUCTION

The menopausal transition is a progressive endocrinologic continuum that takes reproductive-aged women from regular, cyclic, predictable menses that are characteristic of ovulatory cycles, to a final menstrual period associated with ovarian senescence and menopause. With improvements in medical treatment and increased focus on preventive health care, average life expectancy has increased. Most women can now expect to live at least one third of their lives in the menopause. Specifically, it is projected that by 2020, approximately 52 million women will be aged 55 years and older (U.S. Census Bureau, 2000). Thus, this age group has aptly been called "the next frontier in women's health care", as health and well-being is an important concern for this large and growing population of American women (Frackiewicz, 2000).

DEFINITIONS

The term *menopause* refers to a point in time that follows 1 year after the cessation of menstruation. The *postmenopause* describes those years following this point. The average age of women experiencing their final menstrual period (FMP) is 51.5 years, but cessation of menses due to ovarian failure may occur at any age. *Premature ovarian failure* refers to cessation of menses before age 40 and is associated with an elevated follicle-stimulating hormone (FSH) level (see Chap. 16, Hypergonadotropic Hypogonadism (Premature Ovarian Failure)).

The older terms *perimenopause* or *climacteric* generally refer to the time period in the late reproductive years, usually late 40s to early 50s. Characteristically, it begins with menstrual cycle irregularity and extends to 1 year after permanent cessation of menses. The more correct terminology for this time is *menopausal transition* . This transition typically develops over a span of 4 to 7 years, and the average age at its onset is 47 years (McKinlay, 1992).

Menopausal transition has been divided into an early and a late phase by Soules and others at the Stages of Reproductive Aging Workshop (STRAW) held in July, 2001 (Fig. 21-1). The purpose of the STRAW report was to clarify the stages and nomenclature of normal female reproductive aging. The group concluded that because the terms *perimenopause* and *climacteric* are not used consistently, they should be used only with patients and in the lay press and not in scientific papers, and the term *menopausal transition* is the preferred term (Soules, 2001).

FIGURE 21-1

The stages of reproductive aging. *(Redrawn from Soules, 2001, with permission).*

The STRAW report divides reproductive and post-reproductive life into several stages. The anchor for the staging system is the FMP, and the age range and duration of each stage varies. Five stages precede and two stages follow the FMP. Stage â€“5 refers to the early reproductive period, stage â€“4 to the reproductive peak, and stage â€“3 to the late reproductive period. Stage â€“2 refers to the early menopausal transition (MT) and stage â€“1 to the late MT. Stage +1a refers to the first year after FMP, stage +1b refers to years two to five postmenopause, and stage +2 refers to the ensuing later postmenopausal years.

In the early menopausal transition (stage â€“2), a woman's menstrual cycles remain regular, but the interval between cycles may be altered by 7 or more days. Typically, cycle lengths become shorter. Compared with younger women, FSH levels are elevated, and serum estrogen levels may be increased in the early follicular phase. Normal ovulatory cycles may be interspersed with anovulatory cycles during this transition, and conception can occur unexpectedly. The late menopausal transition (stage â€“1) is characterized by two or more skipped menses and at least one intermenstrual interval of 60 days or more due to longer and longer periods of anovulation (Soules, 2001).

All of the above definitions are currently the best description of a woman's transit through menopause, but will certainly be subject to modification in the future.

INFLUENTIAL FACTORS

A number of environmental, genetic, and surgical influences may alter ovarian aging. For example, Wallace and associates (1979) found that smoking advances the age of menopause by about 2 years. In addition, chemotherapy, pelvic radiation, ovarian surgery may also lead to an earlier age of menopause. During the menopausal transition, more erratic fluctuations in female reproductive hormones can lead to an array of physical and psychological symptoms as outlined in Table 21-1 (Bachmann, 2001; Dennerstein, 1993).

Table 21-1 Symptoms Associated with Menopausal Transition

Changes in menstrual patterns

Shorter cycles are typical (by 2â€“7 days)
Longer cycles are possible
Irregular bleeding (heavier, lighter, with spotting)
Vasomotor symptoms
Hot flushes
Night sweats
Sleep disturbances
Psychological and metal disturbances
Worsening premenstrual syndrome
Depression
Irritability
Mood swings
Loss of concentration
Poor memory
Sexual dysfunction
Vaginal dryness
Decreased libido
Painful intercourse
Somatic symptoms
Headache
Dizziness
Palpitations
Breast pain and enlargement
Joint aches and back pain
Other symptoms
Urinary incontinence
Dry, itchy skin
Weight gain

PHYSIOLOGICAL CHANGES

Hypothalamus-Pituitary-Ovarian Axis Changes

During the reproductive life of a woman, gonadotropin-releasing hormone (GnRH) is released in a pulsatile fashion by the arcuate nucleus of the medial basal hypothalamus. It binds to GnRH receptors on the pituitary gonadotrophs to stimulate cyclic luteinizing hormone (LH) and FSH release. These gonadotropins, in turn, stimulate the production of the ovarian steroids: estrogen, progesterone, and also inhibin. During the reproductive years, estrogen and progesterone exert positive and negative feedback on pituitary gonadotropin production and on the amplitude and frequency of GnRH release. Produced in the granulosa cells, inhibin exerts important negative feedback influence over FSH secretion from the pituitary. This tightly regulated endocrine system leads to ovulatory menstrual cycles that are regular and predictable.

The transition from ovulatory cycles to menopause typically begins in the late 40s and in early menopausal transition (Stage â€“2). Levels of FSH rise slightly and lead to an increased ovarian follicular response with overall higher estrogen levels (Jain, 2005; Klein, 1996). There is an increase in serum estrogen levels, produced from an increased number of follicles in the stimulated cohort responding to rising FSH levels. Also, during this time ovarian follicles undergo an accelerated rate of loss until eventually, in the late menopausal transition, the supply of follicles is depleted. These changes, including the increase in FSH levels, reflect the reduced quality and capability of aging follicles to secrete inhibin (Santoro, 1996, Reyes, 1977). As follicular depletion continues, episodes of anovulation become more common (Roseff, 1989). With ovarian failure in the menopause (stage +1b), ovarian steroid hormone release ceases, and the negative-feedback loop is opened. Subsequently, GnRH is released at maximal frequency and amplitude. As a result, circulating FSH and LH levels rise up to fourfold higher than in the reproductive years (Klein, 1996).

Ovarian Changes

Ovarian senescence is a process that has been shown to actually begin in utero within the embryonic ovary due to programmed oocyte atresia (see Fig. 14-1). From birth onward, primordial follicles are continuously being activated, mature partially, and then regress. This follicular activation continues in a constant pattern that is independent of stimulation by the pituitary. Richardson and colleagues (1987) performed a quantitative histologic study of the endometrium and a randomly selected ovary. These were coupled with a single hormonal measurement and a reproductive history, from each of 17 women aged 44 to 55 years who underwent oophorectomy and hysterectomy for uterine leiomyomas or menorrhagia. The six women who reported regular cycles had an average of 1700 follicles in the selected ovary compared with an average of 180 follicles in the ovaries of those who reported irregular cycles. Evidence such as this suggests that regular follicular activation is altered during late reproductive life.

A more rapid depletion of ovarian follicles starts in the late 30s and early 40s and continues until a point at which the menopausal ovary is virtually devoid of follicles (Figs. 21-2 and 21-3). An average woman may experience about 400 ovulatory events during her reproductive lifetime. This represents a very small percentage of the 6 to 7 million oocytes present at the 20th week of gestation, or even the 700,000 oocytes present at birth. The process of atresia of the nondominant cohort of follicles, largely independent of menstrual cyclicity, is the prime event that leads to the eventual loss of ovarian activity and menopause.

Note preponderance of primordial follicles. **B.** High-power image of primordial follicles. **C.** The menopausal ovary shows abundance of atretic follicles and persistent corpora albicans. *(Courtesy of Dr. Raheela Ashfaq).*

Adrenal Steroid Level Changes

With advancing age, adrenal production of dehydroepiandrosterone sulfate (DHEAS) declines. Adrenal hormone levels have been studied in aging women by Labrie (1997) and Burger (2000), each with their colleagues. They found that in women aged 20 to 30 years, DHEAS concentrations peaked, with an average of 6.2 micromoles, and then decreased steadily. In women 70 to 80 years of age, DHEAS levels were diminished by 74 percent to 1.6 micromoles. Other adrenal hormones decrease with aging as well. Androstenedione peaks at ages 20 to 30 years and then decreases to 62 percent of this peak level in women aged 50 to 60 years. Pregnenolone diminishes by 45 percent from reproductive life to menopause. The ovary contributes to the production of these hormones during the reproductive years, but after menopause, only the adrenal gland continues this hormone synthesis.

Burger and associates (2000) prospectively studied 172 women during the menopausal transition as a part of the Melbourne Women's Midlife Health Project. By analyzing hormone levels longitudinally in these patients, no relationship between a woman's final menstrual period and the decline in DHEAS was noted. Advancing age, regardless of menopausal status, determined DHEAS decline.

Sex Hormone-Binding Globulin Level Changes

The principal sex steroids, estradiol and testosterone, circulate in the blood bound to a glycoprotein carrier produced in the liver, known as sex hormone-binding globulin (SHBG). Production of SHBG declines after the menopause and may lead to increased levels of free or unbound estrogen and testosterone.

Endometrial Changes

Microscopic changes in the endometrium directly reflect the level of systemic estrogen and progesterone and thus may change dramatically depending on the phase of menopausal transition. During early menopausal transition, the endometrium may reflect ovulatory cycles, which are prevalent during this time. During the later stage of menopausal transition, anovulation is common, and the endometrium will display estrogen's effect when unopposed by progesterone. Accordingly, proliferative changes or disordered proliferative changes are frequently findings on pathologic examination of endometrial biopsy samples. After menopause, the endometrium becomes atrophic due to lack of estrogen stimulation (Fig. 21-4).

MENSTRUAL DISTURBANCES

Menses may be irregular in more than one half of all women during menopausal transition (Treloar, 1981). In all women, regardless of menopausal status, the etiology of abnormal bleeding should be determined (see Chap. 8). Anovulation is the most common cause of erratic bleeding during the transition, although endometrial hyperplasia, estrogen-sensitive neoplasms such as endometrial polyps and uterine leiomyomas, and pregnancy should always be considered. Many women in their 40s do not consider themselves fertile and will cease using contraception.

Endometrial cancer should be suspected in any woman in menopausal transition with abnormal uterine bleeding. The overall incidence of endometrial cancer is approximately 0.1 percent of women in this group per year, but in women with abnormal uterine bleeding, the risk increases to 10 percent (Lidor, 1986). Malignant precursors of endometrial cancer such as complex endometrial hyperplasia become more common during the menopausal transition, and early diagnosis with endometrial biopsy should be done to exclude malignancy (see Chap. 33, Endometrial Hyperplasia).

Although endometrial neoplasia is the greatest concern during this time, endometrial biopsy frequently reveals a non-neoplastic endometrium displaying estrogen effects unopposed by progesterone. In premenopausal women, this results from anovulation. In postmenopausal women, unopposed estrogen may be derived from extragonadal endogenous estrogen production, which may result from increased aromatization of androgen to estrogen due to obesity. In addition, decreased SHBG levels lead to increased levels of free, and therefore bioavailable, estrogen (Moen, 2004). Unopposed estrogen administration can also account for these effects in postmenopausal women.

EVALUATION OF ABNORMAL BLEEDING

Sonography

Transvaginal sonographic measurement of endometrial thickness can be used in postmenopausal women to avoid endometrial biopsy (see Chap. 2, Transvaginal Sonographic Endometrial Evaluation). Speroff (2005) recommends that in postmenopausal women with abnormal bleeding, endometrial biopsy is not required if the endometrial thickness is less than 5 mm, because the risk of endometrial hyperplasia or cancer is low. Evidence is lacking about the application of this criterion to premenopausal women. However, a biopsy is indicated in a premenopausal patient if a clinical history suggests long-term unopposed estrogen exposure, even if the endometrial thickness is "normal" (5 to 12 mm).

Endometrial Biopsy

The diagnostic approach to a woman in menopausal transition with abnormal bleeding has evolved over the last century from operating room dilatation and curettage (D&C), to outpatient vacuum-suction curettage, to eventually the Pipelle plastic catheter (see Fig. 8-5) (Stovall, 1991; Guido, 1995).

Less than 10 percent of postmenopausal women cannot be adequately evaluated by office biopsy. Inability to enter the uterine cavity is the most common reason for failure. In such instances, pretreatment with the prostaglandin E_1 analog misoprostol (Cytotec, Pharmacia, Morpeth, UK), 100 mg orally the night before and morning of biopsy, may be warranted. Misoprostol softens the cervix and typically allows passage of a Pipelle through a stenotic os. This may avert the need for forceful dilatation and curettage.

Hysteroscopy

Hysteroscopy is also useful to evaluate abnormal uterine bleeding. This tool allows for evaluation of focal intrauterine lesions and targeted biopsy of specific lesions such as submucous leiomyomas, endometrial polyps, or focal areas of endometrial hyperplasia or endometrial cancer (see Section 41-35, Hysteroscopy). Patients with a stenotic cervical os that does not allow an in-office endometrial biopsy to be performed can be pretreated with misoprostol 100 mg orally the night before and the morning of scheduled hysteroscopy, to ease cervical dilation.

Central Thermoregulation Changes

INCIDENCE

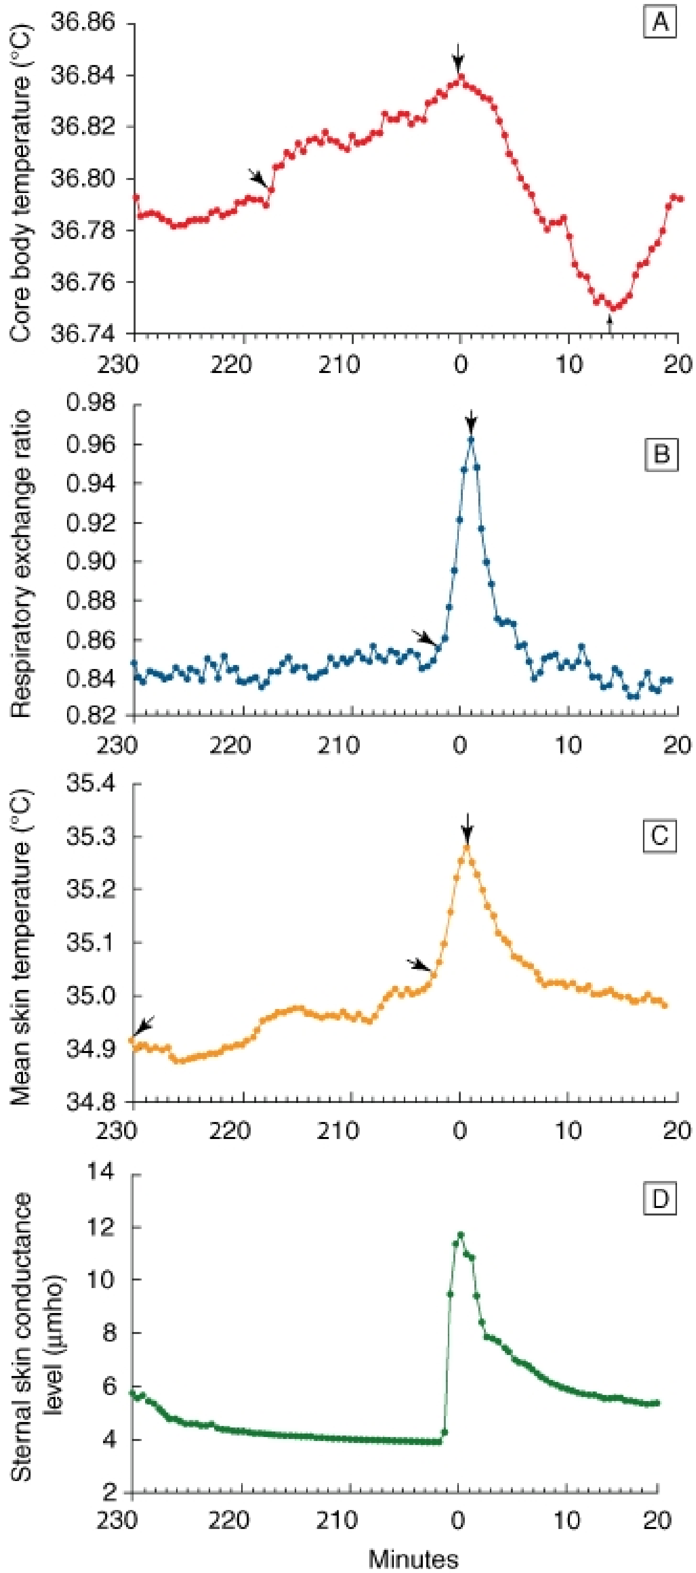
Vasomotor symptoms, which may be described as hot flashes, hot flushes, and night sweats, are the most common medical

complaint of women during menopausal transition. Kronenberg (1990) tabulated all of the published epidemiologic studies and determined that vasomotor symptoms developed in 11 to 60 percent of menstruating women during the transition. In the Massachusetts Women's Health Study, the incidence of hot flushes increased from 10 percent during the premenopausal period to approximately 50 percent after cessation of menses (McKinlay, 1992). Hot flushes begin an average of 2 years before the FMP, and 85 percent of women who experience them will continue to experience them for more than 1 year. Of these women, 25 to 50 percent will have hot flushes for 5 years, and 15 percent may experience them for >15 years (Kronenberg, 1990).

VASOMOTOR SYMPTOMS

Thermoregulatory and cardiovascular changes that accompany a hot flush have been well documented. An individual hot flush generally lasts 1 to 5 minutes, and skin temperatures rise because of peripheral vasodilation (Kronenberg, 1990). This change is particularly marked in the fingers and toes, where skin temperature can increase 10 to 15Â°C. Most women sense a sudden wave of heat that spreads over the body, particularly on the upper body and face. Sweating begins primarily on the upper body, and it corresponds closely in time with an increase in skin conductance (Fig. 21-5). Sweating has been observed in women during 90 percent of hot flushes (Freedman, 2001).

FIGURE 21-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Physiologic changes (means) during a hot flush. **A.** Core body temperature. **B.** Respiratory exchange ratio. **C.** Skin temperature. **D.** Sternal skin conductance. Time 0 is the beginning of the sternal skin conductance response. *(Redrawn from Freedman, 1998, with permission).*

Increases in both awake and sleep systolic blood pressure are noted with hot flushes (Gerber, 2007). In addition, heart rate increases 7 to 15 beats per minute at approximately the same time as peripheral vasodilatation and sweating. Heart rate and skin blood flow usually peak within 3 minutes of the onset of the hot flush. Simultaneously with sweating and peripheral vasodilation, the metabolic rate also significantly rises. Hot flushes may also be accompanied by palpitations, anxiety, irritability, and panic.

Five to 9 minutes after a hot flush begins, core temperature decreases 0.1 to 0.9Â°C due to heat loss from perspiration and increased peripheral vasodilation (Molnar, 1981). If the heat loss and sweating is significant, a woman may experience chills. Skin temperature gradually returns to normal, sometimes taking 30 minutes or longer.

PATHOPHYSIOLOGY OF VASOMOTOR SYMPTOMS

Despite the prevalence and impact of hot flushes, the pathophysiology of vasomotor symptoms is not clearly understood (Bachmann, 2005). Some dysfunction of central thermoregulatory centers in the hypothalamus is likely the cause of this common symptom. The medial preoptic area of the hypothalamus contains the thermoregulatory nucleus responsible for regulating perspiration and vasodilatation, which is the primary mechanism of heat loss in humans. If exposed to temperature changes, this nucleus activates these heat dissipation mechanisms. These maintain core body temperature in a regulated normal range, called the *thermoregulatory zone* .

Estrogens

Certainly, estrogens play a vital role in the development of hot flushes (Fig. 21-6). Although there is no clear correlation between the two, estrogen withdrawal or rapid fluctuation in levels, rather than low estrogen concentration, is suspected (Erlik, 1982; Overlie, 2002). This hypothesis is supported by the fact that women with gonadal dysgenesis (Turner syndrome), who lack normal estrogen levels, do not experience hot flushes unless first exposed to estrogen and then withdrawn from treatment.

FIGURE 21-6

Serotonin (5-HT) receptors are those for the neurotransmitter serotonin **A.** Estrogen stabilizes the CNS thermoregulatory set point and leads to a normal response. **B.** During menopausal transition, decreased estrogen levels lead to instability of the set point and an altered response to external thermal stimuli. **C.** Gradually over time, the set point becomes stable again. Alternatively,

pharmacologic intervention with exogenous estrogen or selective serotonin reuptake inhibitors (SSRIs) may also stabilize the set point. 5-HT = 5-hydroxytryptamine; LHRH = luteinizing hormone-releasing hormone; SNRI = selective norepinephrine reuptake inhibitor. *(Redrawn from Stearns, 2002, with permission.)*

Neurotransmitters

Although estrogen withdrawal clearly has a significant impact on hot flush development, recent research has demonstrated that other factors are involved (Bachmann, 2005). For example, Freedman and colleagues (1998, 2001) hypothesized that changes in neurotransmitter levels may contribute to hot flushes. Altered neurotransmitter concentrations may create a narrow thermoregulatory zone and a lowered sweating threshold. Thus, even subtle changes in core body temperature may trigger heat loss mechanisms.

Norepinephrine

Norepinephrine is thought to be the primary neurotransmitter responsible for lowering the thermoregulatory setpoint and triggering the heat loss mechanisms associated with hot flushes (Rapkin, 2007). Plasma levels of norepinephrine metabolites are increased before and during hot flushes. Moreover, studies have shown that norepinephrine injections can increase core body temperature and induce a heat loss response (Freedman, 1990). Conversely, medications that decrease norepinephrine levels may reduce vasomotor symptoms (Laufer, 1982).

Estrogens are known to modulate adrenergic receptors in many tissues. Freedman and colleagues (2001) suggested that hypothalamic α_2 -adrenergic receptors are decreased by menopause-related decreases in estrogen levels. They showed that a decline in presynaptic α_2 -adrenergic receptors leads to increased norepinephrine levels, thereby causing vasomotor symptoms.

Serotonin

Serotonin is likely to be another neurotransmitter that is involved in the pathophysiology of hot flushes (Slopien, 2003). Estrogen withdrawal is associated with a decreased blood serotonin level, which is followed by upregulation of serotonin receptors in the hypothalamus. Activation of specific serotonin receptors has been shown to mediate heat loss (Gonzales, 1993). However, the role of serotonin in central regulatory pathways is complex because binding at some serotonin receptors can exert negative feedback on other serotonin receptor types (Bachman, 2005). Therefore, the effect of a change in serotonin activity depends on the type of receptor activated.

In sum, these and other studies suggest that reductions and significant fluctuations in estradiol levels lead to a decline in inhibitory presynaptic α_2 -adrenergic receptors and an increase in hypothalamic norepinephrine and serotonin release. Norepinephrine and serotonin lower the setpoint in the thermoregulatory nucleus and allows heat loss mechanisms to be triggered by subtle changes in core body temperature.

Sleep Dysfunction and Fatigue

Sleep disruption is a common complaint of women with hot flushes. Women may awake several times during the night and may be drenched in sweat. Disturbed sleep can lead to fatigue, irritability, depressive symptoms, cognitive dysfunction, and impairment in daily functioning.

The relationship between hot flushes and impaired sleep has been studied (Table 21-2). Hollander (2001) studied a cohort of late reproductive-aged women and found that women with a greater incidence of hot flushes were more likely to report poor sleep than were women with fewer vasomotor symptoms. Kravitz and colleagues (2003) found that the incidence and severity of sleep disorders appeared to be increased in late menopausal transition and at menopause, the periods during which women are most likely to experience vasomotor symptoms.

Table 21-2 Insomnia by Severity of Hot Flushes and Menopausal Symptoms						
	Insomnia Symptoms ≥ 6 mo					
Variable	**DIS**	**DMS**	**NRS**	**At Least 1 Symptom**	**GSD**	**DSM-IV Insomnia Diagnosis**
Hot flashes (%)						
None (n = 673)	7.7	30.5	6.8	12.9	36.0	10.5
Mild (n = 172)	11.6	47.1	15.1	15.1	52.9	23.3
Moderate (n = 89)	19.1	56.2	25.8	28.1	66.3	30.3
Severe (n = 48)	35.4[a]	68.8[a]	35.4[a]	52.1[a]	81.3[a]	43.8[a]
Menopausal status (%)						
Premenopause (n = 562)	9.4	30.2[a]	9.3	15.3	36.5	13.0
Perimenopause (n = 219)	16.0	49.8	20.1[a]	23.3	56.6[a]	26.0
Postmenopause (n = 201)	9.0	44.8	8.0	12.9	50.7	14.4

Many women begin to have prolonged feelings of fatigue, exhaustion, and lack of energy during menopausal transition. Fatigue may be related to night sweats and difficulty sleeping or an independent risk factor that is yet to be identified. Common sense education for patients during menopausal transition may prove valuable (Table 21-3).

Table 21-3 Fatigue Prevention Instructions
Obtain adequate sleep every night
Exercise regularly to reduce stress
Avoid long work hours and maintain your personal schedule
If stress is environmental, take vacations, switch jobs, or approach your company or family to help resolve sources of your stress
Limit intake of alcohol, drugs, and nicotine
Eat a healthy and well-balanced diet
Drink adequate amounts water (8 to 10 glasses) during the early part of the day
Consider seeing a specialist in menopausal medicine

RISK FACTORS FOR VASOMOTOR SYMPTOMS

Several risk factors have been associated with an increased probability of hot flushes, including surgical menopause, race/ethnicity,

body mass, and smoking. Surgical menopause is associated with a 90-percent probability of hot flushes during the first year after oophorectomy, and symptoms can be more abrupt and severe than those associated with natural menopause. Research has also demonstrated that the prevalence of vasomotor symptoms varies among racial and ethnic groups. Hot flushes appear to be more common in African-American than in white women and are more common among white than among Asian women (Gold, 2001; Kuh, 1997).

The impact of body mass on hot flush frequency is not clear. Some investigators have reported that thinner women are more likely to experience hot flushes, whereas others have found that heavier women are more commonly affected (Erlik, 1982; Wilbur, 1998). Other risk factors include early menopause, low circulating levels of estradiol, a sedentary lifestyle, smoking, and use of selective estrogen receptor modulators (SERMs) (Bachman, 2005). In addition, women exposed to high ambient temperatures may experience more frequent and severe hot flushes. Randolph (2005) found that the incidence of hot flushes at 31Â°C may be four times as great as that at 19Â°C. A thorough discussion of treatment options for hot flushes is found in Chapter 22, Treatment of Vasomotor Symptoms.

Bone Metabolism and Structural Changes

Normal bone is a dynamic, living tissue that is in a continuous process of destruction and rebuilding. This bone remodeling, also described as *bone turnover* , allows adaptation to mechanical changes in weight bearing and other physical activities.

The skeleton consists of two bone types (Fig. 21-7). Cortical bone is the bone of the peripheral skeleton (arms and legs) and accounts for 80 percent of total bone. Trabecular bone is the bone of the axial skeleton, which includes the spinal column, pelvis, hip, and proximal femur. The process of bone remodeling involves a constant resorption of bone, carried out by multinucleated giant cells known as *osteoclasts* , and a concurrent process of bone formation, completed by *osteoblasts* (Fig. 21-8).

FIGURE 21-7

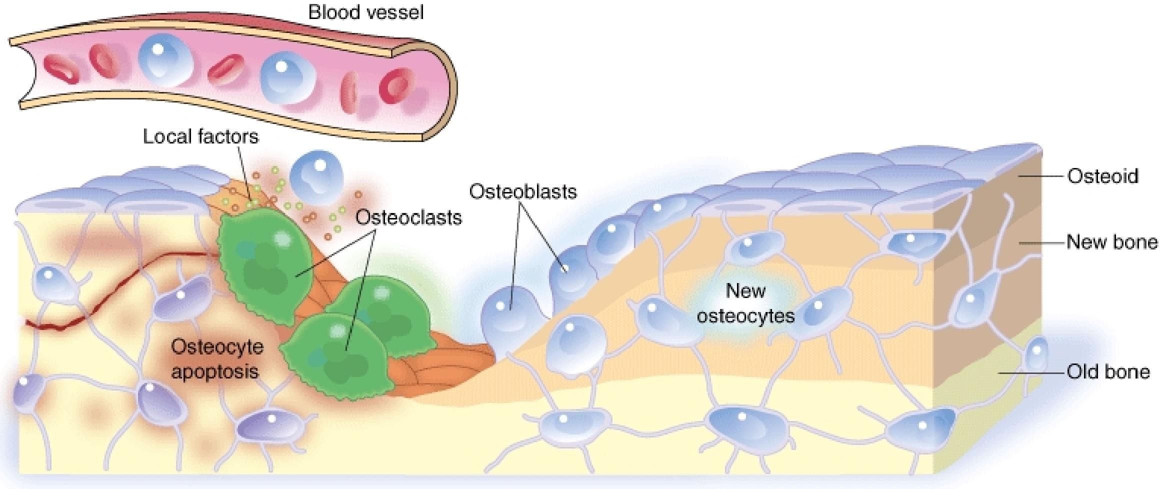
FIGURE 21-8



Bone remodeling. Osteoclasts resorb matrix, whereas osteoblasts deposit new lamellar bone. Osteoblasts that are trapped in the matrix become osteocytes. Others die or form new, flattened osteoblast lining cells. *(Redrawn from Seeman, 2006, with permission).*

Peak bone mass is influenced by heredity and endocrine factors, and there is only a relatively narrow window of opportunity for acquiring bone mass. Almost all bone mass in the hip and the vertebral bodies will be accumulated in young women by late adolescence, so the years immediately following menarche (ages 11 to 14 years) are especially important (Sabatier, 1996; Theintz, 1992). Following this peak, bone resorption is normally coupled to bone formation such that positive bone balance is achieved when skeletal maturity is attained, typically at ages 25 to 35 years.

Thereafter, bone mass declines at a slow, steady rate of about 0.4 percent each year. During menopause, the rate increases to 2 to 5 percent per year for the first 5 to 10 years and then slows to 1 percent per year. The subsequent risk of fracture from osteoporosis will depend on bone mass at the time of menopause and the rate of bone loss following menopause (Riis, 1996).

Osteopenia and Osteoporosis

INCIDENCE

These bone disorders are characterized by a progressive reduction in bone mass (typically greater in trabecular bone) and predispose patients to fractures in the spine, hips, and other sites. It is estimated that 7.8 million American women have osteoporosis and 21.8 million have low bone density in the hip.

OSTEOPOROSIS SEQUELAE

Fractures are the most debilitating and costly consequence of osteoporosis. Approximately 1.5 million Americans experience osteoporotic fractures each year. The spine, hip, and wrists are most commonly fractured (Kanis, 1994). Osteoporotic fractures are associated with significant morbidity and mortality, and the risk of dying following a clinical fracture is reportedly twofold higher than for persons without fractures. The overall mortality from hip fracture alone is estimated to be 30 percent. In addition, only 40 percent of those who sustain a hip fracture are capable of returning to their prefracture level of independence. Osteoporotic fractures are associated with high health care resource utilization and carry an economic burden in the United States of approximately 20 billion dollars annually (Kanis, 1994).

Pathophysiology

Osteoporosis is a skeletal disease in which bone strength is compromised, resulting in an increased risk for fracture. A major proportion of bone strength is determined by bone mineral density (BMD), which explains why BMD measurements are effective tools for identifying patients at high risk for fractures. However, bone strength and fracture risk are also affected by other qualities of bone such as rates of remodeling, size and geometry, microarchitecture, mineralization, damage accumulation, and matrix quality (Kiebzak, 2003).

Primary osteoporosis refers to bone loss associated with aging and menopausal estrogen deficiency. As its levels fall after menopause, estrogen's regulatory effect on bone resorption is lost. As a result, bone resorption is accelerated and is usually not balanced by compensatory bone formation. This accelerated bone loss is most rapid in the early postmenopausal years (Gallagher, 2002). If osteoporosis is caused by other diseases or medications, the term *secondary osteoporosis* is used (Stein, 2003).

The amount of bone at any point in time reflects the balance of the osteoblastic (building) and osteoclastic (resorbing) activities, which are influenced by a multitude of stimulating and inhibiting agents (Canalis, 2007). As noted above, both aging and a loss of estrogen lead to a significant increase in osteoclastic activity. In addition, a decrease in calcium intake or impaired absorption of calcium from the gut lowers the serum level of ionized calcium. This stimulates parathyroid hormone (PTH) secretion to mobilize calcium from bone by stimulation of osteoclastic activity (Fig. 21-9). Increased PTH levels stimulate the production of vitamin D. In turn, increases in vitamin D lead to increased serum calcium levels by several effects: (1) stimulates osteoclasts to remove calcium from bone, (2) increases intestinal calcium absorption, (3) stimulates renal calcium reabsorption (Holick, 2007).

FIGURE 21-9

Vitamin D metabolism. Provitamin D (7-dehydrocholesterol) in the skin is converted to cholecalciferol by ultraviolet (UV) light. Cholecalciferol and ergocalciferol (from plants) are transported to the liver, where they undergo hydroxylation to form the major circulating form of vitamin D. A second hydroxylation step occurs in the kidney and results in the hormonally active vitamin D [$1{,}25(OH)_2 D_3$], also known as calcitriol. This activation step is mediated by 1α-hydroxylase and is regulated by parathyroid hormone (PTH), Ca^{2+} levels, and vitamin D [$1{,}25(OH)_2 D_3$]. The activity of 1α -hydroxylase is stimulated by PTH and inhibited by Ca^{2+} and $1{,}25(OH)_2 D_3$. Vitamin D increases bone resorption, Ca^{2+} absorption from the intestine, renal Ca^{2+} reabsorption, and PTH production by the parathyroid glands. The overall effect of vitamin D is to increase plasma Ca^{2+} concentrations. *(From Molina, 2006, with permission).*

In normal premenopausal women, this series of events leads to increased serum calcium levels, and PTH levels return to normal. In menopausal women, estrogen deficiency leads to a greater responsiveness of bone to PTH. Thus, for any given level of PTH, there is more calcium removed from bone. This condition raises the level of serum calcium, which in turn lowers the level of PTH and

decreases the vitamin D level.

DIAGNOSIS OF OSTEOPOROSIS

Bone mineral density (BMD) is the standard used for bone mass determination and is commonly assessed with dual-energy x-ray absorptiometry (DEXA) of the lumbar spine, radius, and hip (Fig. 21-10) (Marshall, 1996). The lumbar spine contains primarily trabecular bone, which comprises 20 percent of the skeleton. This bone is less dense than cortical bone and has a faster bone remodeling rate. Therefore, early rapid bone loss can be determined by evaluation of this site. Cortical bone is denser and more compact bone and comprises 80 percent of bone. It is most abundant in the long-bone shafts of the appendicular skeleton. The greater trochanter and femoral neck contain both cortical and trabecular bone, and these sites are ideal for the prediction of hip fracture risk in older women (Miller, 2002).

Dual-energy x-ray absorptiometry (DEXA) scans. **A.** DEXA report describing normal hip density. **B.** DEXA report describing osteopenia of the hip. **C.** DEXA report describing normal vertebral body density. **D.** DEXA report describing vertebral body osteoporosis. BMC = bone mineral content; BMD = bone mineral density.

Normative bone mineral density values for sex, age, and ethnicity have been determined. For diagnostic purposes, results of BMD testing should be reported as *T-scores.* These measure in standard deviations (SDs) the variance of an individual's BMD from that expected for a person of the same sex at peak bone mass (25 to 30 years). A T-score of â€"2.0 in a woman, for example, means that her BMD is two SDs below the average peak bone mass for a young woman. Definitions from the National Osteoporosis Foundation include those found in Table 21-4. A fourth category "severe osteoporosis" has been suggested to describe patients who have a T-score below â€"2.5 and who have also suffered a fragility fracture. These are fractures caused by a fall from standing height or lower.

Table 21-4 Criteria for Interpretation of Bone Mineral Density

- Normal BMD is defined as a T-score between +2.5 and â€“1.0. The patient's BMD lies between 2.5 standard deviations (SDs) above the young adult mean and 1 SD below the young adult mean.
- Osteopenia (low BMD) is associated with a T-score between â€“1.0 and â€“2.5, inclusive. Osteopenia is also a term used by radiologists to indicate that bones on a radiograph appear to be of decreased mineral content.
- Osteoporosis is defined as a T-score lower than â€“2.5.

From the National Osteoporosis Foundation, 2003.

Patients will also be assigned a *Z-score,* which is the standard deviation between the patient's measurement and average bone mass for a patient with the same age and weight. Z-scores lower than â€“2.0 (2.5 percent of the normal population of the same age) require diagnostic evaluation for secondary osteoporosis, which includes causes other than menopausal bone loss (Faulkner, 1999). Similarly, any patient with osteoporosis should be screened for other conditions that lead to osteoporosis (Table 21-5).

Table 21-5 Secondary Causes of Osteoporosis and Recommended Testing

- Primary hyperparathyroidism: serum levels of parathyroid hormone, calcium, phosphorus, and alkaline phosphatase
- Secondary hyperparathyroidism from chronic renal failure: renal function tests
- Hyperthyroidism or excess thyroid hormone treatment: thyroid function tests
- Increased calcium excretion: 24-hour urine collection for calcium and creatinine concentrations
- Hypercortisolism, alcohol abuse, and metastatic cancer: careful history and when indicated appropriate laboratory studies
- Osteomalacia: serum levels of calcium, phosphorus, alkaline phosphatase, and 1,25-dihydroxyvitamin D

The relation between BMD and fracture risk has been calculated in a large number of studies. A meta-analysis by Marshall and colleagues (1996) showed that BMD is still the most readily quantifiable predictor of fracture risk for those who have not yet suffered a fragility fracture. For each standard deviation of BMD below a baseline level (either mean peak bone mass or mean for the reference population of the person's age and sex), the fracture risk approximately doubles (National Osteoporosis Foundation, 2003).

PREVENTION

Many factors have been suggested as predictors of risk of osteoporotic fractures (Table 21-6). The most important predictive factors are bone density in combination with age, fracture history, ethnicity, various drug treatments, weight loss, and physical fitness. The presence of a key risk factor should alert a clinician to the need for further assessment and possibly active intervention, such as calcium therapy coupled with weight-bearing exercise or pharmacologic therapy. Treatment options for osteoporosis are discussed in Chapter 22, Treatment of Osteoporosis.

Table 21-6 Osteoporosis Risk Factors	
Major Risk Factors	**Minor Risk Factors**
Age >65 years	Rheumatoid arthritis
Vertebral compression fracture	Prior history of clinical hyperthyroidism
Fragility fracture after age 40	Chronic anticonvulsant therapy
Family history of osteoporotic fracture	Low dietary calcium intake
Systemic glucocorticoid therapy of >3 months duration	Smoker
Malabsorption syndrome	Excessive alcohol intake
Primary hyperparathyroidism	Excessive caffeine intake
Propensity to fall	Weight <57 kg
Osteopenia apparent on radiography	>10 percent weight loss at age 25
Hypogonadism	Chronic heparin therapy
Early menopause (before age 45)	

Bone Mineral Density

This characteristic of bone is currently the best quantifiable predictor of osteoporotic fracture. Low BMD and other major risk factors combine to further increase a person's risk of fracture (National Osteoporosis Foundation, 2003). Therefore, BMD should be measured in a postmenopausal woman older than 50 years with one of the other major risk factors for fracture or in any woman older than 65.

Risk factors for osteoporotic fracture are not independent of one another. They are additive and must be considered in the context of baseline age and sex-related risks of fracture. For example, a 55-year-old woman with low BMD is at significantly less risk than a 75-year-old woman with the same low BMD. Similarly, a woman with low BMD and a prior fragility fracture is at considerably greater risk than another person with the same low BMD and no prior fracture.

Osteoporotic fractures occur most commonly in men and women older than 65 years. Medical interventions have only been demonstrated to be effective in preventing fractures in populations with an average age older than 65 years. However, most currently approved osteoporosis therapies prevent or reverse bone loss if initiated at, or soon after, the age of 50 years. Therefore, it seems prudent to begin the identification of people at high risk for osteoporosis in their 50s.

Fragility Fracture

As stated earlier, a prior fragility fracture places a person at increased risk for another fracture. The increased risk is 1.5- to 9.5-fold depending on age at assessment, number of prior fractures, and site of the incident fracture (Melton, 1999). Vertebral fractures have been best studied in this regard. The presence of a vertebral fracture increases the risk of a second vertebral fracture at least fourfold. A study of a placebo group in a major clinical trial showed that 20 percent of those who experienced a vertebral fracture during the period of observation had a second vertebral fracture within 1 year (Lindsay, 2001). Vertebral fractures are also indicators of increased risk of fragility fractures at other sites, such as the hip. Similarly, wrist fractures predict vertebral and hip fractures.

Aging

Age is clearly a major contributor to fracture risk. As summarized in a review by Kanis and others (2001) the 10-year probability of experiencing a fracture of forearm, humerus, spine, or hip increases as much as eightfold between ages 45 and 85 years for women.

Race

Osteoporosis is most common in menopausal white women, and in 2003 the National Osteoporosis Foundation found that 20 percent of these women have osteoporosis and 52 percent have low bone density. Although persons of any ethnicity can develop osteoporosis, data from the Third National Health and Nutrition Examination Survey (NHANES III) indicate that the risk is highest among non-Hispanic white and Asian women and lowest among non-Hispanic black women.

Genetics

Genetic influence on osteoporosis and BMD is extremely important. It has been estimated that heredity accounts for 50 to 80 percent of BMD variability (Ralston, 2002). These influences have been the subject of major scientific investigations, and a number of genes have been associated with osteoporosis. These discoveries, however, have yet to result in a clinical application. A family history of osteoporotic fracture has been best studied with respect to hip fracture. The Study of Osteoporotic Fractures, for example, identified a maternal history of hip fracture as a key risk factor for hip fracture in a population of elderly women (Cummings, 1995). In addition, a history of hip fracture in a maternal grandmother also carries an increased risk of this fracture.

Fall Precautions

Fractures are frequently associated with falls. Therefore, a history of falls or factors that increase rates of these accidents should be included in a risk assessment. Factors include those associated with general frailty, such as reduced muscle strength (inability to rise from a chair without assistance), impaired balance, low body mass, and reduced visual acuity (World Health Organization, 1994). Alcohol use and excessive use of sedative prescription drugs are also an important risks for falls.

Systemic Glucocorticoids

Therapy with glucocorticoids lasting more than 2 to 3 months is a major risk factor for bone loss and fracture, particularly among postmenopausal women and men older than 50 years. Most reviews and guidelines describe a daily dose of prednisone that is ≥ 7.5 mg as the threshold for assessment and clinical intervention to prevent or treat glucocorticoid-induced osteoporosis (Canalis, 1996).

Screening

As a result of these risk factors, programs to confirm osteoporosis and determine disease severity should include BMD measurements in all menopausal women who: (1) are aged 65 years or older, (2) have one or more risk factors for osteoporosis, or (3) sustain fractures. If therapy to increase bone mineral density is instituted, density should be monitored.

Prophylaxis for osteoporosis with weight-bearing exercise and calcium intake should begin in adolescence (Recker, 1992). Calcium supplementation in prepubertal and pubertal girls improves bone accrual, an important effect that should have long-lasting beneficial consequences (Bonjour, 2001; Rozen, 2003; Stear, 2003).

Cardiovascular Changes

CARDIOVASCULAR DISEASE RISK

Cardiovascular disease (CVD), including coronary heart disease, congestive heart failure, and stroke, is the leading cause of death in both men and women (Minino, 2002). Most cardiovascular disease develops from atherosclerotic changes in the major blood vessels. Risk factors are the same for men and women and include family history of cardiovascular disease, hypertension, smoking, diabetes mellitus, abnormal cholesterol/lipoprotein profile, and obesity. Age alone is a significant predictor of CVD risk in men and women.

Before menopause, women have a much lower risk for cardiovascular events compared with men their age. Reasons for protection from CVD in premenopausal women are complex, but a significant contribution can be assigned to the greater high-density lipoprotein (HDL) levels in younger women, which is an effect of estrogen. However, after menopause this benefit disappears over

time such that a 70-year-old woman begins to have a risk identical to that of a male of comparable age (Matthews, 1989). The risk of CVD increases exponentially for women as they enter menopause and estrogen levels decline (Matthews, 1994; van Beresteijn, 1993). This becomes vitally important for women in menopausal transition, when preventive measures can significantly improve both the quality and the quantity of their lives (see Chap. 1, Cardiovascular Disease). Statistics indicate that one in three women older than 65 years has some evidence of CVD. By age 55, 20 percent of all deaths are caused by CVD, and 30 to 40 percent of women eventually die of CVD.

The relationship between menopause and CVD incidence was first examined in the Framingham cohort of 2,873 women (Kannel, 1987). There was a trend for a two- to sixfold higher incidence of CVD in postmenopausal women compared with premenopausal women in the same age range. This pattern is similar to that seen with the incidence of osteoporosis, which increases dramatically during menopausal transition. Moreover, the increases in CVD associated with the menopausal transition are observed regardless of the age at menopause. These and other data indicate that withdrawal of estrogen may be associated with an increased risk of CVD.

CARDIOVASCULAR DISEASE PREVENTION

Importantly, clinicians should offer strategies to their postmenopausal patients that help to prevent or delay the onset of CVD. Since recent data have questioned the widespread prescription of hormones to avert this common problem, other strategies must be considered (see Chap. 22). As a part of the Women's Health Initiative (WHI), an observational study of women's activity levels, was conducted. Manson and colleagues (2002) identified the cardiovascular benefits of physical activity. They determined that walkingâ€”as well as vigorous exerciseâ€”prevented cardiovascular events in postmenopausal women regardless of their age, body mass index (BMI), or ethnic background. As expected, a sedentary lifestyle correlated directly with an increase in the risk for a coronary event (McKechnie, 2001).

Central adiposity is a risk factor for coronary heart disease in women and is associated with a relatively androgenic hormonal state (see Fig. 17-8). Central fat distribution, also termed truncal obesity, in women is positively correlated with increases in total cholesterol, triglyceride, and LDL levels, and negatively correlated with HDL levels (Haarbo, 1989). This atherogenic lipid profile associated with abdominal adiposity is at least partly mediated through interplay with insulin and estrogen. A strong correlation exists between the magnitude of the worsening in cardiovascular risk factors (lipid and lipoprotein changes, blood pressure, and insulin levels) and the amount of weight gained during the menopausal transition (Wing, 1991). Davies (2001) and Matthews (2001) have shown that weight gain at menopause is not an effect of hormonal changes, but rather reflects diet, exercise, and a reduction of metabolic rate associated with aging.

Lipids

Physiologic levels of estrogen are known to help maintain favorable lipoprotein profiles in women. Specifically, throughout adulthood HDL levels are approximately 10 mg/dL higher in women, and this difference continues throughout the postmenopausal years. Moreover, total cholesterol and low-density lipoprotein (LDL) levels are lower in premenopausal women than in men (Jensen, 1990; Matthews, 1989). After menopause and with the subsequent decrease in estrogen, this favorable effect on lipids is lost. High-density lipoprotein levels decrease and total cholesterol levels increase.

After menopause, the risk of coronary heart disease doubles for women and at approximately age 60, the atherogenic lipids reach levels higher than those in men. Brunner (1987) and Jacobs (1990), each with their colleagues, have prospectively documented the strong association between total cholesterol and coronary heart disease in women, however, coronary heart disease risk appears at higher total cholesterol levels for women than for men. Women with a total cholesterol concentration greater than 265 mg/dL have rates of coronary heart disease three times those of women with low or normal levels. A low HDL-cholesterol level is also a strong predictor of CVD in women. The average HDL cholesterol in women is 55 to 60 mg/dL and a decrease in HDL cholesterol of 10 mg/dL increases coronary heart disease risk by 40 to 50 percent (Kannel, 1987).

Despite these changes in atherogenic lipids following menopause, total cholesterol and LDL levels can be favorably reduced by dietary modifications, estrogen treatment, and lipid-lowering medications (Matthews, 1994).

Coagulation

Changes in clotting parameters are known to occur with aging. Fibrinogen, plasminogen activator inhibitor-1, and factor VII

increase and cause a relatively hypercoagulable state. This is thought to contribute to increases in cardiovascular and cerebrovascular disease in older women.

Weight Gain and Fat Distribution

Weight gain is a common complaint among women in the menopausal transition. With aging, a woman's metabolism slows, reducing her caloric requirements. If eating and exercise habits are not altered, weight is gained (Matthews, 2001). Specifically, Espeland and colleagues (1997) characterized the weight and fat distribution of 875 women in the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial and correlated the impact of lifestyle, clinical, and demographic factors. They found that women aged 45 to 54 years had significantly greater increases in weight and in hip circumference than those aged 55 to 65 years. Reported that overall baseline physical activity and baseline leisure and work activities were strongly related to weight gain in the PEPI cohort. Women who reported more activity gained less weight than less active women.

Weight gain during this period is associated with fat deposition in the abdomen, which increases the likelihood of developing insulin resistance and subsequent diabetes mellitus and heart disease (Dallman, 2004; Wing, 1991). In addition, as reviewed by Baumgartner (1995), data from the Rosetta Study and the New Mexico Aging Process Study show that older adults have higher percentages of body fat than younger adults at any age due to the loss of muscle mass with aging.

Numerous other factors underlie weight gain and include genetic factors, neuropeptides, and adrenergic nervous system activity (Milewicz, 1996). Although many women believe that noncontraceptive estrogen therapy causes weight gain, recent results from clinical trials and epidemiologic studies indicate that the impact of menopausal hormone therapy on body weight and girth, if any, is to decrease slightly the rate of age-related increases.

Dermatologic Changes

Skin changes that may occur in the menopausal transition include hyperpigmentation (age spots), wrinkles, and itching. These are caused in part from skin aging, which results from the synergistic effects of intrinsic aging and photo-aging (Guinot, 2005). In addition, hormonal aging of the skin is thought to be responsible for many dermal changes. These changes include a reduced thickness due to reduced collagen content, a decrease in sebaceous gland secretion, a loss of elasticity, diminished blood supply, and epidermal changes (Wines, 2001).

Although the impact of hormone deficiency on skin aging has been widely studied, its distinction from the effects of intrinsic aging, photo-aging, and other environmental insults is difficult.

Dental Changes

Dental problems may also develop as estrogen levels wane in late menopausal transition. The buccal epithelium undergoes atrophy due to estrogen deprivation, resulting in decreased saliva and sensation. A bad taste in the mouth, increased incidence of cavities, and tooth loss also may occur (Krall, 1994).

Oral alveolar bone loss is strongly correlated with osteoporosis and can lead to tooth loss. The beneficial effect of estrogen on skeletal bone mass is also manifested on oral bone. Even in women without osteoporosis, there is a correlation between spinal bone density and number of teeth. Tooth loss is also strongly correlated with the use of cigarettes and the adverse effect they have on dental health (Krall, 1994).

Breast Changes

The breast undergoes change during menopause mainly because of hormonal withdrawal. In premenopausal women, estrogen and progesterone exert proliferative effects on ductal and glandular structures, respectively. At menopause, withdrawal of estrogen and progesterone leads to a relative reduction in breast proliferation. A significant reduction in the volume and percentage of dense tissue on mammography is noted, and these areas become replaced with adipose tissue.

Central Nervous System

SLEEP DYSFUNCTION

Difficulties in sleep onset and sleep maintenance are common in menopausal women. Sleep fragmentation is commonly associated

with hot flushes and results in daytime fatigue, mood lability, irritability, and problems with short-term memory (Owens, 1998). Even women with few vasomotor symptoms may experience insomnia and associated menopause-related mood symptoms (Erlik, 1982; Woodward, 1994). At times, short-term use of pharmacologic sleep aids are indicated, and these are listed in Table 1-21.

As women age, they are more likely to experience lighter sleep and are awakened more easily by pain, sound, or bodily urges. Health issues and other chronic conditions experienced by women, or not infrequently their spouse or bedmate, are likely to further disrupt sleep. Arthritis, carpal tunnel syndrome and other painful conditions, chronic lung disease, heartburn, and certain medications that are known to disrupt sleep may have a dramatic impact on quality and quantity of restful sleep. Nocturia, urinary frequency, and urgency, all of which are more common in menopausal women, are also important factors.

Sleep disordered breathing (SDB), which includes various degrees of pharyngeal obstruction, is much more common in menopausal women and their mates. In women, SDB is commonly associated with increased body mass and declining estrogen and progesterone levels. Loud snoring may develop due to upper airway obstruction and can range in severity from upper airway resistance to obstructive sleep apnea (Gislason, 1993). In all these examples, treatment of underlying heath conditions should be the focus to improve patient sleep.

COGNITIVE DYSFUNCTION

Memory decreases with advancing age. Although no direct effect of lowered estrogen levels on memory and cognition has been determined, many investigators suspect a relationship to, or an acceleration of, cognitive decline during menopause. Cognitive functioning was assessed in a cohort study of reproductive-aged and postmenopausal women not using hormone replacement therapy. In postmenopausal patients, cognitive performance declined with advancing age. This was not the case for reproductive-aged women. Premenopausal women in their forties were less likely to exhibit cognitive decline compared with postmenopausal patients in the same decade of life. These investigators concluded that there is accelerated deterioration of some forms of cognitive function after menopause (Halbreich, 1995).

Factors accelerating cerebral degenerative changes represent potentially modifiable risks for cognitive decline (Kuller, 2003; Meyer, 1999). Investigators have studied putative risk factors that accelerate subtle cognitive decline and dementia. They have correlated them with repeated measures of cerebral atrophy, computed tomography (CT) densitometry, and cognitive testing among neurologically and cognitively normal, aging volunteers. Risk factors for decreased cerebral perfusion and thinning of gray and white matter densities include transient ischemic attacks (TIAs), hyperlipidemia, hypertension, smoking, excess alcohol consumption, and male gender, which would imply lack of estrogen. The authors suggested interventions to control those risk factors amenable to modification.

Psychosocial Changes

Few studies of women's health in the menopausal years have formally assessed well-being and the psychosocial aspects of menopausal transition. Dennerstein and colleagues (1994) studied women during midlife to determine whether menopausal status, social circumstance, health status, interpersonal stress, attitude, and lifestyle behavior correlated with well-being in midlife. These investigators found that menopausal status had little effect on well-being. However, well-being was found to be significantly related to current perceived health status, general psychosomatic symptoms, general respiratory symptoms, history of premenstrual symptoms, and interpersonal stress. Attitudes toward aging and menopause were also significantly associated with well-being scores. Other investigators have found that psychosocial issues are common during this time, and do relate them directly to the fluctuation in hormonal levels.

Psychological and cognitive symptoms may develop during menopausal transition and include depression, mood changes, poor concentration, and impaired memory. Although many women perceive these changes as age-related aggravations or attribute them to worsening premenstrual syndrome (PMS), these symptoms may in fact result from changes in reproductive hormones (Bachmann, 1994; Schmidt, 1991).

More importantly, the menopausal transition is a complex sociocultural as well as a hormonal event. Psychosocial factors also may contribute to mood and cognitive symptoms during this phase, since women entering menopausal transition may face additional emotional stress from dealing with adolescents, onset of a major illness, caring for an aging parent, divorce or widowhood, career

change, or retirement (LeBoeuf, 1996).

Lock (1991) suggests that part of the stress reported by Western women is clearly culture-specific. Western culture emphasizes beauty and youth, and as women grow older, some suffer from a perceived loss of status, function, and control (LeBoeuf, 1996). However, the end of predictable menstruation and the end of fertility may be important to a woman simply because it is a change, no matter how aging and the end of reproductive life are viewed by that woman and by her culture (Frackiewicz, 2000). For some women, the approach of menopause may also be perceived as a significant loss, both to women who have accepted childbearing and rearing as their major life roles and those who are childless, perhaps not by choice. For these reasons, impending menopause may be perceived as a time of loss, when depression and other psychological disorders may develop (Avis, 2000).

Contemporary findings have dispelled myths that natural menopause, itself, is associated with depressed mood (Ballinger, 1990; Busch, 1994). That said, in general, there is a high percentage of subjects with recurrent depression at menopause, and a high percentage experiencing their first episode of depression during menopausal transition (Freeman, 2007; Spinelli, 2005).

It has been suggested that the hormonal fluctuations during early menopausal transition are responsible, in part, for this affective instability. Similarly, surgical menopause induces mood changes because of the rapid hormonal loss at this time. Soares (2005) hypothesizes that a major component of the reported emotional distress during menopausal transition may be causally related to high and erratic estradiol levels. For example, Ballinger and colleagues (1990) have shown that increases in stress hormones (and probably symptoms that are stress related) are physiologically linked with high estrogen levels. They also showed that women who had abnormal scores on psychometric tests early after menopause had higher estradiol levels than those with lower scores. In prospective, physiological studies of women reporting severe PMS, Spinelli and associates (2005) have shown that estrogen levels are correlated with the intensity of menopausal symptoms. A randomized, placebo-controlled menopause treatment study evaluated administered standard doses of conjugated equine estrogen (0.625 mg/d), which significantly improved sleep, but also showed an estrogen-related increase of inward-directed hostility (Schiff, 1980).

Libido Changes

Although the relationship between circulating hormones and libido has been extensively investigated, definitive data are lacking. Many studies demonstrate that other factors besides menopause may account for changes in libido (Gracia, 2007). Avis and colleagues (2000) studied sexual function in a subgroup of 200 women in the Massachusetts Women's Health Study II who underwent natural menopause. None took hormone treatment, and all these women had sexual partners. Menopausal status was observed to be significantly related to decreased sexual interest. However, after adjustment for physical and mental health, smoking, and marital satisfaction, menopause status no longer had a significant relationship to libido. Dennerstein (2005) prospectively evaluated 438 Australian women during 6 years of their menopausal transition. Menopause was significantly associated with dyspareunia and indirectly with sexual response. Psychological factors of feelings for one's partner, stress, and other social factors also indirectly affected sexual functioning.

Other investigators have demonstrated that sexual problems are more prevalent after menopause. A longitudinal study of women during the menopausal transition until at least 1 year after the final menstrual period demonstrated a significant decrease in the rate of weekly coitus. Patients reported a significant decrease in the number of sexual thoughts, sexual satisfactions, and vaginal lubrication after becoming menopausal (McCoy, 1985). In a study of 100 naturally menopausal women, both sexual desire and activity decreased compared with that during the premenopausal period. Women reported loss of libido, dyspareunia, and orgasmic dysfunction, with 86 percent reporting no orgasms after menopause (Tungphaisal, 1991).

Lower Reproductive Tract Changes

Estrogen receptors have been identified in the vulva, vagina, bladder, urethra, pelvic floor musculature, and endopelvic fascia. These structures thus share a similar hormonal responsiveness, including susceptibility to the estrogen deprivation that can develops after menopause, in the postpartum period during lactation, or with hypothalamic amenorrhea.

Without estrogen's trophic influence, the vagina loses collagen, adipose tissue, and ability to retain water (Sarrel, 2000). As vaginal walls shrink, rugae flatten, and the vagina attains a flat-walled, pale-pink appearance. The surface epithelium thins to a few layers of cells, markedly reducing the ratio of superficial to basal cells. As a result, the vaginal surface is left friable and prone to bleeding

with minimal trauma. The blood vessels in the vaginal walls narrow, and over time the vagina itself contracts and loses flexibility. In addition, vaginal pH becomes more alkaline and a pH greater than 4.5 is typically observed with estrogen deficiency (Caillouette, 1997; Roy, 2004). An alkaline pH creates a vaginal environment less hospitable to lactobacilli and more susceptible to infection by urogenital and fecal pathogens. In addition to vaginal changes, as estrogen production wanes in the later menopausal transition, the vulvar epithelium gradually atrophies and secretions from sebaceous glands diminish. The labia minora become paler and smaller. As a result of these changes, the clinical syndromes associated with vulvovaginal atrophy include vaginal dryness and irritation, dyspareunia, and recurrent urinary tract infections (Society of Obstetricians and Gynaecologists of Canada, 2005).

Dyspareunia and Sexual Dysfunction

Complaints of dyspareunia and other forms of sexual dysfunction are extremely common in menopausal patients. Laumann and associates (1999) studied the prevalence of sexual dysfunction in postmenopausal women and found that 25 percent complained of some degree of dyspareunia. They found that painful intercourse correlated with sexual problems, including lack of libido, arousal disorder, and anorgasmia. Although dyspareunia in this population is generally attributed to vaginal dryness and mucosal atrophy secondary to loss of ovarian hormones, prevalence studies suggest a decrement in all aspects of female sexual function are associated with midlife (Dennerstein, 2005).

The reduction in ovarian estrogen results in a decline in vaginal lubrication, atrophic vaginitis, and decreased blood flow and vasocongestion with sexual activity. This leads to genital changes including ischemia, thinning skin, and decline in size of the introitus, labia, vagina, and clitoris (Alexander, 2003). Reduced testosterone levels have been implicated in genital atrophy as well.

Urogenital conditions such as prolapse or incontinence correlate strongly with sexual dysfunction (Barber, 2002; Salonia, 2004). Patients with urinary incontinence are likely to have pelvic-floor hypotonus dysfunction which may cause pain on deep penetration due to lack of pelvic stability. Hypertonic or dyssynergic pelvic-floor muscles, which are commonly seen in patients with urinary frequency, constipation, and vaginismus, are often associated with superficial pain and friction during intercourse (Handa, 2004). The presence of organ prolapse contributes to dyspareunia as does a history of a gynecologic surgical procedure that may cause dyspareunia by shortening the vagina (Goldberg, 2001).

Other medical conditions such as arthritis, hip or lumbar joint pain, or fibromyalgia may contribute to vaginal or pelvic pain with intercourse. Pain may be due to radiation of pain from trigger points in the trunk, buttocks, or pelvic-floor muscles, or from possible pudendal nerve entrapment. Chronic pelvic pain or abdominal and vulvar scars or adhesions may also be contributors to sexual dysfunction (see Chap. 11, Chronic Pelvic Pain).

Urogenital

As was stated earlier, there are estrogen and progesterone receptors in most pelvic floor muscles and ligaments. Due to low estrogen production in late menopause or after oophorectomy, genitourinary atrophy may lead to a variety of symptoms that affect quality of life. Urinary symptoms may include dysuria, urgency, and recurrent urinary tract infections (Notelovitz, 1989).

Specifically, thinning of urethral and bladder mucosa may lead to urethritis with dysuria, urge incontinence, and urinary frequency. In addition, urethral shortening associated with menopausal atrophic changes may result in genuine stress urinary incontinence. For example, Bhatia and colleagues (1989) showed that estrogen therapy may improve or cure stress urinary incontinence in more than 50 percent of treated women, presumably by exerting a direct effect on urethral mucosa coaptation (see Chap. 23, Urethral Coaptation). Accordingly, a trial of hormone therapy should be considered prior to surgical correction of incontinence in women with vaginal atrophy.

Alternatively, some studies have not found an association between incontinence and menopausal status. Sherburn and colleagues (2001) performed a cross-sectional study of Australian women aged 45 to 55 years. In this population, they identified a 15-percent prevalence of incontinence. Associated risk factors included gynecologic surgery, higher BMI, urinary tract infections (UTIs), constipation, and multiparity. Subsequently, these investigators studied a subset of 373 premenopausal females during 7 years to determine if menopausal transition itself was associated with an increased incidence of incontinence. In this group of women, the overall incidence of incontinence was 35 percent, with no increase associated with menopause. Incontinence was most closely related to hysterectomy during the course of the study.

In addition to incontinence, pelvic organ prolapse rates increase with advancing age. Importantly, vaginal relaxation with cystocele, rectocele, and uterine prolapse are not a direct consequence of estrogen deprivation, as many factors play a role in pelvic floor relaxation (Fig. 21-11) (see Chap. 24, Pathophysiology).

PATIENT EVALUATION

Clinical goals of the menopausal transition evaluation are to optimize a woman's health and well-being during and after this transition. This is an excellent time for a detailed health evaluation, including a complete medical history, physical examination, and laboratory studies. Risk factors for such common health problems such as obesity, osteoporosis, heart disease, diabetes mellitus, and certain cancers should be assessed, and then managed (see Chap. 1, Preventive Care). Counseling about diet, exercise, alcohol moderation, and smoking cessation are imperative if applicable.

DIAGNOSIS

The diagnosis of menopausal transition can usually be made with documentation of age-appropriate symptoms and careful physical examination (Table 21-7). Clearly, a 50-year-old woman with menstrual irregularity, hot flushes, and vaginal dryness should be considered to be in menopausal transition. Other testing such as FSH or estradiol levels can be performed to document ovarian failure. However, in the menopausal transition group, FSH levels may be normal. Even when much younger women present with similar symptoms, evaluation should also include FSH measurement. If ovarian failure occurs before 40 years, it is usually pathologic. Thus, investigation for chromosomal abnormalities, infections, autoimmune disorders, galactosemia, cigarette smoking, or iatrogenic causes such as radiation or chemotherapy should be considered (see Chap. 16, Heritable Disorders).

Table 21-7 Differential Diagnosis of Menopausal Symptoms
Hot flushes, vasomotor symptoms
Hyperthyroidism
Pheochromocytoma
Febrile illness
Anxiety and psychological symptoms
Vaginal dryness, dyspareunia
Bacterial vaginosis
Yeast infection
Pelvic pathology
Poor vaginal lubrication
Marital discord
Primary osteoporosis
Osteomalacia
Primary and secondary hyperparathyroidism
Hyperthyroidism or excess thyroid replacement
Excess corticoid therapy
Increased calcium excretion
Abnormal uterine bleeding
Anovulation
Endometrial cancer
Cervical cancer
Endometrial hyperplasia
Endometrial polyps
Uterine leiomyoma
Urogenital atrophy
Hormone treatment

Physical Examination

A thorough general physical examination should be performed during patient visits to document changes associated with aging and menopausal transition.

CONSTITUTIONAL

Height, weight, and BMI are recorded and can be used to counsel women about physical exercise and weight loss or weight gain. Moreover, assessment of weight distribution and waist circumference may identify those with truncal obesity, who carry greater risks for other comorbidity. Height loss may be associated with osteoporosis and spinal compression fractures. Therefore yearly height measurement is warranted. Blood pressure monitoring effectively screens for hypertension, which is common in this population.

COGNITIVE

Cognitive decline is unusual in a woman during menopausal transition, but common complaints of forgetfulness or scattered thinking may be part of the normal aging process. In patients who are concerned about cognitive decline, referral to a neurologist is encouraged.

PSYCHOSOCIAL

Evaluation of psychosocial well-being should be part of transition assessment. Clinicians may inquire directly about depression, anxiety, and sexual functioning, or may choose to administer a simple questionnaire to assess for psychosocial issues (see Chap. 13, Diagnosis of Mood Disorders).

DERMATOLOGIC

Skin changes associated with estrogen deficiency include skin thinning and wrinkling. In addition, various skin lesions are commonly associated with aging and photo-aging. Careful inspection for abnormal nevi or excessive sun exposure may prompt referral to a dermatologist for further skin cancer evaluation.

BREAST

During menopausal transition, estrogen levels fall and glandular breast tissue is gradually replaced by fatty tissue. Breast tissue and axillae are carefully inspected and palpated. Nipple discharge, skin changes, nipple inversion, and masses should be documented and evaluated (see Chap. 12, Evaluation of a Breast Lump).

PELVIC EXAMINATION

Examination of the vulva may demonstrate loss of the connective tissue that results in shrinkage of the labia majora. The labia minora may disappear completely, and there is often a narrowing of the introitus. The vulva should be examined for redness, atrophy, or scarring. In those with pain, scar tissue from a past tear or episiotomy, traumatic delivery, or surgery should be noted. Specific areas of tenderness can often be localized with a methodical evaluation of the vulva. Touch with a cotton-swab may locate and reproduce a patient's pain (see Fig. 4-11).

Vaginal examination will typically reveal a narrow vaginal canal and thin vaginal epithelium. The classic appearance of vaginal atrophy includes loss of rugae and a pale, dry vaginal mucosa. Epithelial tissues are often friable, and submucosal petechial hemorrhages may be seen. Markers of vaginal atrophy include a vaginal pH greater than 5.0 and a change in the vaginal wall's maturation index toward basal cell predominance. Culture of the vagina may reveal pathogenic bacteria not normally found in the vagina.

In addition to a standard gynecologic evaluationâ€”that is, bimanual and speculum examinationâ€—external and internal assessment should focus on pelvic and vaginal muscular tone and strength, as well as mobility and integrity of the fascia and connective tissues. The degree of introital flexibility, mucosal dryness, or atrophy is determined. Integrity of the pelvic organs and possible prolapse of the bladder, uterus, or rectum is evaluated by having the patient perform a Valsalva maneuver and observing for bulging of a cystocele, rectocele, or cervical or vaginal prolapse.

Laboratory Testing

GONADOTROPIN LEVELS

There are biochemical changes present, of which a woman may be unaware, prior to evidence of cycle irregularity. For example, in the early follicular phase of the menstrual cycle in many women older than 35 years, FSH levels may rise without a concurrent luteinizing hormone (LH) elevation. This finding is associated with a poor prognosis for future fertility. Specifically, a day-3 FSH level greater than 10 mIU/mL is used in some in vitro fertilization (IVF) programs to route patients into donor egg programs (see Chap. 20, Correction of Diminished Ovarian Reserve). An FSH level greater than 40 mIU/mL has been used to document ovarian failure associated with the menopause.

ESTROGEN LEVELS

Estrogen levels may be normal, elevated, or low depending on the stage of menopausal transition. Only at menopause are estrogen levels extremely low or undetectable. Additionally, estrogen levels may be used to assess women's response to hormone treatment. Most clinicians prefer to reach a physiologic serum estradiol range of 50 to 100 pg/mL when selecting and adjusting replacement therapy. Women who receive estradiol pellets as replacement therapy may have elevated serum estradiol values from 300 to 500 pg/mL. These high levels are not uncommon with this replacement method but should be discouraged.

ESTROGEN MATURATION INDEX

The maturation index (MI) is an inexpensive means to evaluate hormonal influences in women. A specimen to measure the MI may be collected during a vaginal speculum examination at the same time a Pap smear is performed. The index report is read from left to right and refers to the percentage of parabasal, intermediate, and superficial squamous cells appearing on a smear, with the total sum of all three values equaling 100 percent (Fig. 21-12) (Randolph, 2005). For example, an MI of 0:40:60 represents 0 percent parabasal cells, 40 percent intermediate cells, and 60 percent superficial cells. This MI reflects adequate vaginal estrogenization. A shift to the left indicates an increase in parabasal or intermediate cells, which denotes low estrogen levels. Conversely, a shift to the right reflects an increase in the superficial or intermediate cells, which is associated with higher estrogen levels.

Photomicrographs of cytologic specimens illustrate key points of the maturation index. This index provides insight into the cytohormonal status of the patient and is based on a count of parabasal, intermediate, and superficial (P:I:S) cells. Generally, a predominance of superficial or superficial and intermediate cells (**A** and **B**) is seen in reproductive-aged women. A predominance of intermediate cells (**C**) is seen in the luteal phase, pregnancy, with amenorrea, and in newborns, premenarchal girls, and women in early menopausal transition. A predominance of parabasal cells (**D**) is seen in menopausal patients with atrophy. *(Courtesy of Dr. Raheela Ashfaq).*

An ideal MI vaginal specimen consists of freely exfoliating squamous cells from the upper third of the vaginal wall. Avoiding the cervical area, the vaginal wall secretions are gently scraped with a spatula or saline-moistened swab. Immediately after collection, the specimen is transferred to a microscope slide. Cells are either suspended in a small amount of saline (as in a wet prep) or smeared to the slide and fixed with 95-percent ethanol spray fixative.

URINARY AND SERUM MARKERS OF BONE RESORPTION AND FORMATION

Remodeling is a normal, natural process that maintains skeletal strength, enables repair of microfractures, and allows calcium homeostasis. During remodeling, osteoblasts synthesize a number of cytokines, peptides, and growth factors that are released into the circulation. Their concentration thus reflects the rate of bone formation. Bone formation markers include serum osteocalcin, bone-specific alkaline phosphatase, and procollagen I carboxy terminal propeptide (PICP) (Table 21-8).

Table 21-8 Analytes Considered Markers of Bone Resorption and Formation

Resorption	Formation
Urinary calcium	Bone-specific alkaline phosphatase
Tartrate resistant acid phosphatase	Osteocalcin
Bone sialoprotein	Procollagen I extension propeptides
Cross-links	Carboxy terminal (PICP)
Pyridinoline	Amino terminal (PINP)
Deoxypyridinoline	
N-telopeptide	
C-telopeptide	
C-terminal telopeptide of type I collagen	

PICP = procollagen I propeptide, c-terminal; PINP = procollagen I propeptide, n-terminal.

Osteoclasts produce bone degradation products that are also released into the circulation and are eventually cleared via the kidney. These include collagen cross-linking peptides and pyridinolines, which can be measured in the blood or urine and enable estimation of bone resorption rates. Bone resorption markers include urinary hydroxyproline, urinary pyridinoline (PYR), and urinary deoxypyridinoline (D-PYR), as well as collagen type I cross-linked N telopeptide (NTX) and collagen type I cross-linked C telopeptide (CTX).

Markers of bone formation and resorption are of value in estimating bone-remodeling rates. These biochemical markers may be used to identify fast bone losers. Numerous cross-sectional studies have shown that bone remodeling rates as evaluated by markers increase at menopause and remain elevated. Bone remodeling rates in menopausal women correlate negatively with BMD.

Most prospective studies evaluating the relationship between bone remodeling and rates of bone loss have been short-term and have been limited by the precision error of densitometry. Garnero and colleagues (1994) prospectively evaluated the utility of bone markers to identify fast bone losers in a large cohort of healthy menopausal women over 4 years. They found that higher levels of bone formation and resorption markers were significantly associated with faster and possibly greater BMD loss.

Markers of bone resorption may be useful predictors of fracture risk and bone loss. Elevation of these markers may be associated with an increased fracture risk in elderly women, although data are not uniform. The association of markers of bone resorption with hip fracture risk is independent of BMD, but a low BMD combined with high bone resorption biomarker doubles the risk associated with either of these factors alone. Biomarker measurements are also currently limited by their high variability within individuals. Additional studies with fracture endpoints are needed to confirm the usefulness of these markers in individual patients.

Biomarkers may also be of value in predicting and monitoring response to potent antiresorptive therapy in clinical trials. Normalization of bone formation and resorption marker levels following therapy has been observed in prospective trials. Reduction in biochemical marker levels appears to be correlated with a decrease in vertebral fracture incidence in some studies, but is not necessarily always predictive of response to therapies.

Bone remodeling markers should not yet be used for routine clinical management. Additional studies are needed to confirm their use in individual patients. However, with refinement of assay technology and better understanding of biological variability, it is likely that they will become a useful adjunct for risk assessment and management.

THE MATURE WOMAN: INTRODUCTION

The typical "mature woman" is aged 40 years or older and has completed childbearing. During their late 40s, most women enter menopausal transition, and this period of physiologic change is usually completed between ages 51 and 56 (see Chap. 21). Menopause marks a defining point in this transition. Specifically, it is defined by the World Health Organization as the point in time of permanent menstruation cessation due to loss of ovarian function. Clinically, the menopause refers to a point in time that follows 1 year after the cessation of menstruation.

After ovarian senescence, declining estrogen levels have specific effects on many tissues. Some effects lead to physical symptoms, such as vasomotor symptoms and vaginal dryness, whereas others are metabolic and structural changes. These include osteopenia, osteoporosis, skin thinning, fatty replacement of the breast, and genitourinary atrophy. As a result, postmenopausal women have specific issues associated with aging and estrogen loss that may negatively affect their individual health.

For many years menopause was seen as a "deficiency disease" much like hypothyroidism. For this reason, hormone replacement therapy has been used in one form or another for more than 100 years. The history and controversies surrounding this treatment are discussed in detail, as are current recommendations for the treatment of menopausal symptoms.

HORMONE TREATMENT: HISTORY AND CONTROVERSIES

In the recent past, hormone treatment (HT) was prescribed, in good faith, to women for many potential health benefits, based on available observational studies of the time. It was thought that HT, in addition to its beneficial role in prevention and treatment of osteoporosis, could protect against cardiovascular disease, stroke, and dementia. However, recent prospective, randomized, and blinded studies have challenged the validity of earlier observational studies. Thus, clinicians should understand the history and controversies surrounding HT to accurately counsel their patients on the complexities and appropriate use of HT.

Early Estrogen Administration Trends

Estrogen treatment (ET) for menopausal symptom relief gained popularity in the 1960s and 1970s. Author and gynecologist Robert Wilson's book *Feminine Forever* was published in 1968. In it, he wrote that "Women who use the drug (estrogen) will be much more pleasant to live with and will not become dull and unattractive" (Bell, 1990). Wilson was a prolific lecturer. His book was widely read and was influential, in part, for some of the enthusiasm for ET and its "preservation of youth" and prevention of chronic disease.

By the mid-1970s, more than 30 million prescriptions were written for estrogen each year, and half of all menopausal women were using HT for a median of 5 years. Premarin (conjugated equine estrogen, Wyeth Pharmaceuticals, Philadelphia, PA) was the fifth most prescribed drug in the marketplace.

In 1975, a study revealed a connection between endometrial cancer and estrogen replacement. Investigators found a 4.5-times greater risk of this cancer in those using estrogen (Smith, 1975). As a result, the U.S. Food and Drug Administration (FDA) ordered labeling changes to state this higher risk.

Estrogen as a Prevention Tool

In the 1980s, progestins were added to therapy regimens to significantly reduce endometrial cancer risks. During that same time, estrogens were documented by several studies to prevent bone loss (Gambrell, 1983). A number of observational studies also suggested that estrogens prevented development of coronary heart disease and other conditions, such as Alzheimer disease.

However, in 1985, conflicting reports from the Framingham Heart Study and the Nurses' Health Study were published.

The Framingham Heart Study, an observational study of 1,234 women, showed that those who took hormones had a 50-percent elevated risk of cardiac morbidity and more than a twofold risk for cerebrovascular disease (Wilson, 1985). In the same edition of the *New England Journal of Medicine,* the much larger Nurses' Health Study, with 121,964 women, found significantly lower rates of heart disease in postmenopausal women taking estrogen compared with postmenopausal women not taking estrogen (Stampfer, 1985). Numerous subsequent articles published in medical periodicals reported on the protective effects that combination HT provided menopausal women against cardiovascular disease and osteoporosis.

Current thinking is that that these early nonrandomized, unblinded, observational studies included samples of women who were not necessarily representative of the entire population of postmenopausal women. These hormone users tended to have superior health care access and to be thinner, wealthier, and healthier overall (Grodstein, 2003; Prentice, 2006). An additional source of confounding and possible selection bias is suggested to be the timing of initiation of hormone therapy in relation to the underlying state of the vasculature. Some investigators have hypothesized that estrogen may delay the onset of the earliest stages of atherosclerosis, which are more likely to be present in younger women, but it may be ineffective or even trigger events in the presence of existing advanced lesions such as those found in older women (Mendelsohn, 2005). The potential existence of a window of opportunity to reduce cardiovascular disease is supported by animal and laboratory studies (Grodstein, 2003). The impacts of these characteristics, biases, and timing in initiation may have led, in part, to favorable outcomes attributed to estrogen in observational trials.

The Postmenopausal Estrogen/Progestin Interventions Trial

Because of data available in the late 1980s, estrogens were prescribed, not only for vasomotor symptom relief, but also for prevention of other conditions. In 1995, the Postmenopausal Estrogen/Progestin Interventions (PEPI) Trial results were published and suggested benefit for coronary heart disease risk. In this study, menopausal women with a mean age of 56 years were randomly allocated to one of five treatments: (1) placebo, (2) estrogen alone, (3) estrogen plus cyclic medroxyprogesterone acetate (MPA), (4) estrogen plus cyclic micronized progesterone, or (5) estrogen plus continuous MPA (The Writing Group for the PEPI Trial, 1995). Primary outcomes studied in the 875 women evaluated during 3 years included assessment of systolic blood pressure and measurement of serum lipid, insulin, and fibrinogen levels. The PEPI trial documented that low-density lipoprotein cholesterol levels were decreased similarly in all groups administered estrogen compared with placebo. In addition, high-density lipoprotein levels were increased in the four treatment groups receiving estrogen. Levels were most substantially increased in women solely given estrogen. An intermediate effect was noted in those prescribed conjugated equine estrogen (CEE) and micronized progesterone, whereas the smallest increase followed CEE and MPA administration. Fibrinogen was increased in the placebo group compared with groups given hormones. However, no differences were identified among any treatment groups in systolic blood pressure or glucose-challenged insulin levels. Clinical outcomes were also reported, and complications were few. Of these, all occurred in the HT-treated groups and included one cardiac arrest, two myocardial infarctions, and two cerebrovascular events (American College of Obstetricians and Gynecologists, 2004).

Heart and Estrogen/Progestin Replacement Study

With results published in 1998, the Heart and Estrogen/Progestin Replacement Study (HERS) described cardiac morbidity in 2,763 women with pre-existing heart disease (Hulley, 1998). These women received estrogen as secondary prevention for further cardiac disease progression. First-year findings showed an increase in myocardial infarctions (MIs) in women who received CEE with continuous MPA. However, after an average treatment duration of 4 years, there was no difference in risks of cardiovascular death or nonfatal MI between treatment groups, with a hazard ratio of 0.99 (95 percent CI 0.81 to 1.22).

The HERS trial represented the first randomized clinical trial at variance with previous observational data and created significant confusion for both clinicians and their patients. There was still widespread belief that hormones prevented heart disease, but the HERS data caused many clinicians and scientists to begin to seriously question the cardioprotective effects of hormones. In June 2002, the HERS II results were published by Grady and colleagues (2002) and also showed that HT was not beneficial in the secondary prevention of heart disease even after 6.8 years. A subsequent re-analysis of the Nurse's Health Study focusing on early hazard among women initiating HT during the monitoring period showed a similar time trend, with early harm, as did the HERS

trial (Grodstein, 2001).

Women's Health Initiative

After an unsuccessful effort in 1990 to obtain FDA approval for HT as a preventive treatment for coronary heart disease, the need for randomized clinical trials to demonstrate conclusive benefit was widely acknowledged. As a result, before the results from the PEPI trial and HERS trials, the National Institutes of Health (NIH) launched the Women's Health Initiative (WHI) in 1993. This was a major study to evaluate the putative beneficial and protective effects of HT on common chronic diseases of aging. The WHI examined the effect of a combined CEE and MPA drug compared with placebo in 16,608 healthy postmenopausal women aged 50 to 79 years (mean of 63.3 years) who had not had a hysterectomy (Rossouw, 2002). Specific end points were evaluated: coronary heart disease, venous thrombotic events, breast cancer, colon cancer, and bone fractures. Concurrently, the study also compared CEE with placebo in postmenopausal women without a uterus (the estrogen-only arm).

As part of the original WHI study design, investigators predetermined targets for CHD (anticipated benefit) and breast cancer (anticipated risk) as primary disease end points. This design dictated that if the incidence of an end point was exceeded within a given period, the study would be terminated. Moreover, combined end points were weighted into a "global index", which if exceeded within a given time period, would result in study termination. After a mean 5.2 years of monitoring, the estrogen and progestin arm of WHI was halted early upon recommendation of its Data and Safety Monitoring board because overall risks exceeded the benefits. In July 2002, results were released to the media. This preceded journal publication of the data and timely education of health care providers. Chaos ensued while physicians and patients evaluated research facts and before recommendations could be made.

In a subsequent detailed analysis of cardiovascular end points, the hazard for cardiovascular death or nonfatal MI was 1.24 (95 percent CI 1.00 to 154). This translated into 188 actual cases in the hormone group and 147 in the placebo group (Anderson, 2004). However, there were no significant differences in coronary revascularization, hospitalization for angina, confirmed angina, acute coronary syndrome, or congestive heart failure.

To explore the issue of timing of initiation of hormone therapy and the influence on cardiovascular disease, Rossouw and colleagues (2007) did a secondary analysis of the WHI. They looked specifically at the effect of HT on coronary heart disease (CHD) and stroke across categories of age and years since menopause in the combined trial. They found that women who initiated hormone therapy closer to menopause tended to have reduced CHD risk compared with the increase in CHD risk among women more distant from menopause. They found that for women with less than 10 years since menopause began, the hazard ratio for CHD was 0.76; with 10 to 20 years since menopause, 1.10; and with 20 or more years, 1.28.

In evaluating data by age, lower risk was found for young women and higher risk for older patients. Specifically, for the age group of 50 to 59 years, the hazard ratio (HR) for CHD was 0.93 or two *fewer* events per 10,000 person years; for the age group 60 to 69 years, 0.98 or 1 *fewer* event per 10,000 person years; and for those 70 to 79 years, 1.26 or 19 *extra* events per 10,000 person years. Hormone therapy increased the risk of stroke (HR 1.32; 95% CI, 1.12 to 1.56) and risk did not vary significantly by age or time since menopause. Rossouw and colleagues concluded that women who initiated hormone therapy closer to menopause tended to have reduced CHD risk compared with the increase in CHD risk among women more distant from menopause.

Concurrent with the WHI, a similarly constructed study, the Women's International Study of Long Duration Oestrogen after Menopause (WISDOM) began enrollment in 1999. This trial was stopped following halting of the WHI. Analyzing data collected from this study, Vickers and colleagues (2007) found hormone replacement therapy increases cardiovascular and thromboembolic risk when started many years after the menopause. These finding echoed those of the women's health initiative study.

CURRENT APPROACH TO HORMONE REPLACEMENT ADMINISTRATION

Summary of Risks and Benefits

As a result of these and other studies, clinicians now know more about the risks and benefits of HT than ever before. In the many reviews and discussions following WHI, most clinicians agree that HT is associated with an increased risk of CHD in older menopausal women, and an increased risk of breast cancer, stroke, venous thromboembolism, and cholecystitis. Breast cancer appears only to be a risk factor with long-term use (>5 years). Two studies have shown an increase in ovarian cancer risk with

long-term use (>10 years), but not with short-term use (<5 years) (Danforth, 2007; Lacey, 2006). However, other studies have not confirmed this risk (Noller, 2002).

In contrast, several long-term benefits are noted with HT. These include increased bone mineral density and decreased rates of fracture and colorectal cancer. In addition to its individual benefits, HT's effects on mortality rates have been examined. A meta-analysis done by Salpeter and associates (2004) pooled data from 30 randomized trials from 1966 through April 2003. Calculations from 26,708 participants revealed that the total mortality rate associated with HT was 0.98 (95 percent confidence). Of note, HT reduced mortality in women younger than 60 years (odds ratio 0.61) but not in women older than 60 (odds ratio 1.03). These investigators suggest that once coronary heart disease is established, HT has no effect in reversing disease progression. Moreover, the incidence of cardiovascular events can potentially increase in older groups due to an increased risk for blood clots. Similarly, Rossouw's group (2007) showed a nonsignificant tendency for the effects of hormone therapy on total mortality to be more favorable in younger than older women.

Summary of Current Use Indications

Based on current literature, HT is indicated today only for treatment of vasomotor symptoms and vaginal atrophy and for osteoporosis prevention or treatment. The current standard of care dictates re-evaluation of the need for therapy at 6- to 12-month intervals. Hormone therapy should be prescribed in the lowest effective dose for the shortest period of time. Accordingly, bone-specific agents would likely be more appropriate in women requiring long-term osteoporosis prevention or treatment.

For women with a uterus, a progestin should be combined with an estrogen to lower risks of endometrial cancer. Progestins may be prescribed daily with estrogen, and this dosing is termed *continuous therapy* . Amenorrhea typically results from this regimen. Alternatively, estrogen may be administered for 25 days each month and a progestin added for the final 10 days. Drugs are withdrawn for 5 days and endometrial sloughing and bleeding follows. This *cyclic therapy* is most commonly used in those during menopausal transition, whereas continuous therapy is usually selected for women following menopause.

Oral progestins are most commonly prescribed, although a progestin-containing intrauterine device (Mirena, Berlex, Wayne, NJ) provides another option (see Chap. 5, Levonorgestrel-Containing Intrauterine Device). In addition, combined estrogen and progestin products are available for either oral or transdermal use. Low-dose combination oral contraceptives are effective in the young perimenopausal woman and have the additional benefit of pregnancy prevention.

Importantly, estrogen is contraindicated in women who exhibit one or more of the following: known or suspected breast carcinoma, known or suspected estrogen-dependent neoplasia, abnormal genital bleeding of unknown etiology, known or suspected pregnancy, and those with active liver disease (Table 22-1). In addition, data show a twofold increase in the risk of venous thromboembolic events (VTEs) in users of HT. Estrogens, particularly those given orally, stimulate hepatic production of clotting factors. Accordingly, HT is also contraindicated in women with a prior history of VTEs.

Table 22-1 Warnings and Precautions with Estrogen Administration
Estrogen should not be used in women with any of the following conditions: 1. Undiagnosed abnormal genital bleeding 2. Known, suspected, or history of breast cancer 3. Known or suspected estrogen-dependent neoplasia 4. Active deep vein thrombosis, pulmonary embolism, or history of these conditions 5. Active or recent (e.g., within the past year) arterial thromboembolic disease (e.g., stroke or myocardial infarction) 6. Liver dysfunction or disease 7. Known hypersensitivity to the ingredients of the estrogen preparation 8. Known or suspected pregnancy. There is no indication for estrogen in pregnancy. There appears to be little or no increased risk of birth defects in children born to women who have used estrogens and progestins from oral contraceptives inadvertently during early pregnancy
Estrogen should be used with caution in women with the following conditions: 1. Dementia 2. Gallbladder disease 3. Hypertriglyceridemia 4. Prior cholestatic jaundice 5. Hypothyroidism 6. Fluid retention plus cardiac or renal dysfunction 7. Severe hypocalcemia 8. Prior endometriosis 9. Hepatic hemangiomas

From U.S. Department of Health and Human Services, 2005, with permission.

Ultimately, the decision regarding whether or not to begin HT is a personal one, to be decided by the patient with guidance from her health care provider.

SYMPTOMS OF MENOPAUSE

Common early symptoms of menopause include vasomotor symptoms, insomnia, irritability, and mood disorders, which can be caused by vasomotor instability. Physical changes include vaginal atrophy, urinary stress incontinence, and skin atrophy. Long-term health risks that have been attributed to the hormonal changes from menopause include osteoporosis, cardiovascular disease, and in some studies, Alzheimer disease, macular degeneration, and stroke.

Treatment of Vasomotor Symptoms

The most frequent symptom of the menopausal transition is vasomotor symptoms, also known as hot flushes or hot flashes (see Chap. 21, Incidence). Following menopause, hot flushes are still pervasive and are experienced by 50 to 85 percent of postmenopausal women. Significant distress results for approximately 25 percent of women. Sleep disturbances can lead to lethargy and depressed mood.

The frequency of hot flushes does decrease with time. In the PEPI trial, the percentage of women taking placebo who experienced vasomotor symptoms declined from 56 percent at their entry into the study to 30 percent by their third year in the trial (Greendale,

1998). Only a small percentage of women continue to suffer from hot flushes 10 years after their menopause. Fifteen years after menopause, approximately 3 percent of women report frequent hot flushes, and 12 percent report moderate to severe vasomotor symptoms (Barnabei, 2002; Hays, 2003).

HORMONAL THERAPY ESTROGEN

Therapy Effectiveness

Hormonal therapy is the most effective treatment for hot flushes and sleep disturbances, thereby improving quality of life in symptomatic women. The value of such treatment has been demonstrated in numerous randomized controlled trials (RCTs) (Nelson, 2004). Maclennan and associates (2004) performed a systematic review of 24 RCTs involving 3,329 women who had moderate to severe hot flushes. These investigators found that HT reduced the frequency of hot flushes by approximately 18 events per week, that is, approximately 75 percent compared with placebo. The severity of vasomotor symptoms also was reduced significantly. Moreover, in the PEPI trial, all treatment arms were more effective than placebo in reducing vasomotor symptoms. There were no significant differences between specific hormone regimens (Greendale, 1998).

Estrogens Approved for Vasomotor Symptoms

Estrogen can be administered by oral, parenteral, topical, or transdermal routes with similar effects (Table 22-2). Within these groups, several different formulation choices are available. Continuous estrogen therapy is recommended, although doses and route of administration can be changed relative to patient preference. In the United States, oral estrogens are the most popular. Transdermal estrogen patches avoid the liver's first pass effect and offer the convenience of less frequent administration (once or twice weekly). The lowest effective dose and duration of therapy are unknown, but this "mantra" is cited by most major menopause organizations for ensuring safety. For treatment of vasomotor symptoms, the FDA has approved all oral estrogen formulations, most transdermal patch formulations, a topical gel, and one intravaginal estrogen product. However, the low-dose estrogen patch, Menostar, (Berlex, Wayne, NJ) has not been approved for this indication.

Table 22-2 Selected Estrogen and Progestin Preparations for the Treatment of Menopausal Vasomotor Symptoms

Preparation	Generic Name	Brand Name	Doses (mg)
Estrogen[a]			
Oral	Conjugated estrogens	Premarin	0.3, 0.45, 0.625, 0.9, 1.25
	17β-estradiol	Estrace	0.5, 1.0, 2.0
Transdermal	17β-estradiol	Alora	0.025, 0.05, 0.075, 0.1 (patch applied twice weekly)
		Climara	0.025, 0.0375, 0.05, 0.075, 0.1 (patch applied weekly)
Vaginal	Estradiol acetate	Femring vaginal ring[d]	0.05, 0.1 (inserted every 90 days)
Progestogen			
Oral	MPA	Provera	2.5, 5.0, 10.0
	Micronized progesterone	Prometrium	100, 200 (in peanut oil)
Vaginal	Progesterone	Prochieve 4%	45

Combination preparations			
Oral sequential[b]	Conjugated estrogens and MPA	Premphase	0.625 conjugated estrogens plus 5.0 MPA
Oral continuous[c]	Conjugated estrogens and MPA	Prempro	0.625 conjugated estrogens plus 2.5 or 5.0 MPA; 0.45 conjugated estrogens plus 2.5 MPA; or 0.3 or 0.45 conjugated estrogens plus 1.5 MPA
Transdermal continuous[c]	17β-estradiol, norethindrone acetate	Activella	1.0 estradiol plus 0.5 norethindrone
	17β-estradiol, levonorgestrel	Climara Pro	0.045 estradiol plus 0.015 levonorgestrel (patch applied weekly)
	17β-estradiol, norethindrone acetate	CombiPatch	0.05 estradiol plus 0.14 or 0.25 norethindrone (patch applied twice weekly)

MPA = medroxyprogesterone acetate.

[a] Hormone therapy can cause uterine bleeding, breast tenderness, and headache. Doses of estrogen that are approxi-mately biologically equivalent include the following: 0.625 mg of Premarin, 1.0 mg of Estrace, and 0.05 mg of Alora, Climara, or Femring.

[b] The first 14 pills contain estrogen and the subsequent pills (15 through 28) contain estrogen with progestin.

[c] Each pill or patch contains estrogen and progestin.

[d] Femring delivers a higher systemic level of estrogen and should be opposed by a progestin in women with a uterus.

From Grady, 2006, with permission.

Progestins

These alone are somewhat effective for treatment of hot flushes in women for whom estrogen is contraindicated, such as those with history of venous thromboembolism or breast cancer. However, adverse effects that include vaginal bleeding and weight gain may limit their use (see Table 22-2).

Beyond mild reduction in hot flushes, progestins used as agents in combined HT offer only one additional benefitâ€”they provide essential protection against estrogen-induced endometrial hyperplasia and cancer in women with a uterus. Clinical trials have shown that progestins provide no meaningful increase in estrogen's benefits to bone. In addition, progestins may attenuate estrogen's beneficial effects on lipids and blood flow.

"Bioidentical" Hormones

Some women, reacting to the media coverage of the WHI, have come to believe that conventional pharmaceutical estrogens hold a clear and present danger. Ironically, more is known about the absolute risks and benefits of HT than almost any other class of drugs on the market.

Although prescriptions for estrogen and progesterone have declined, the use of "bioidentical" hormones has increased significantly. The lay press and self-help hormone books are replete with information suggesting that bioidentical hormones offer the relief that women need with fewer attendant risks. However, current evidence does not support the safety claims reported in much of the advertising for these products. Specifically, the FDA pronounced: "Other doses of CEE and MPA, and other combinations and dosage forms of estrogens and progestins were not studied in the WHI clinical trials, and in the absence of comparable data, these risks should be assumed to be similar". Thus, these hormones cannot be assumed to be safer than conventional pharmaceutical estrogen or progestins.

CENTRAL NERVOUS SYSTEM AGENTS FOR VASOMOTOR SYMPTOMS

No nonhormonal treatments are currently FDA-approved for management of hot flushes, and long-term studies are not available. However, multiple agents and treatments have been used, and data from short-term trials have been published (Table 22-3). These products provide options for women who decline HT or for those in whom estrogen is contraindicated. However, for many, the side effects or ineffectiveness of these agents compared with HT limits their routine use for this indication.

Table 22-3 Nonhormonal Agents Used as Therapy for Vasomotor Symptoms

Prescription (brand name)	Nonprescription
SSRIs (see Table 13-14)	Black cohosh
Venlafaxine (Effexor)	Dong quai
Fluoxetine (Prozac, Sarafem)	Red clover isoflavones
Paroxetine (Paxil)	Soy isoflavones
Clonidine (Catapres)	Vitamin E
Gabapentin (Neurontin)	
Mirtazapine (Remeron)	
Trazodone (Desyrel)	

SSRI = selective serotonin reuptake inhibitor.

Selective Serotonin Reuptake Inhibitors

Three randomized placebo-controlled trials with the antidepressants venlafaxine (Effexor, Wyeth Pharmaceuticals), fluoxetine (Prozac, Eli Lilly, Indianapolis, IN, and Sarafem, Warner Chilcott, Rockaway, NJ), and paroxetine (Paxil, GlaxoSmithKline, Philadelphia, PA) found modest improvement in hot flushes compared with placebo. Specifically, in a randomized, double-blind, placebo-controlled study, Loprinzi and associates (2000) found that venlafaxine XR decreased hot flush scores by 37 percent with a dosage of 37.5 mg/d, 61 percent with 75 mg/d, and 61 percent with 150 mg/d. Women treated with placebo noted a 27-percent reduction in hot flushes. In 2002, Loprinzi and colleagues studied the effects of fluoxetine, 20 mg/d, on hot flushes. They reported that women treated with the selective serotonin reuptake inhibitor (SSRI) noted only 1.5 fewer vasomotor events compared with those receiving placebo. Finally, in a 6-week trial, Stearns and co-workers (2003) evaluated paroxetine CR, 12.5 mg/d and 25 mg/d dosages, compared with placebo. At both dosages, paroxetine led to approximately three hot flushes per day compared with 1.8 hot flushes per day with placebo. Importantly, benefits of SSRIs should be balanced against drug side effects, which can include nausea, diarrhea, headache, insomnia, jitteriness, fatigue, and sexual dysfunction.

Clonidine

The centrally active α_2 -adrenergic receptor agonist clonidine (Catapres and others), has also been shown to be effective in some clinical trials. Nagamani and colleagues (1987) evaluated clonidine 0.1 mg/d transdermally in an 8-week trial. They reported that 12 of 15 women noted a decrease in vasomotor symptoms compared with 5 of 14 receiving placebo. However, hypotension, dry mouth, dizziness, constipation, and sedation have limited its use. For many women, low-dose clonidine is ineffective, and thus adequate therapy may require substantially higher doses that may magnify side effects.

Gabapentin

Gabapentin (Neurontin, Pfizer, New York, NY) is structurally related to the neurotransmitter γ-aminobutyric acid (GABA), but its exact mechanism of action is unknown. Currently, gabapentin is FDA-approved to treat seizures and neuropathic pain. However, it has extensive off-label use for various other neurologic conditions.

In 2003, Guttuso and associates evaluated the use of gabapentin, 900 mg daily, for treatment of vasomotor symptoms. They found a 45-percent reduction in hot flush frequency compared with a 29-percent reduction with placebo. Adverse effects included dizziness and somnolence. Moreover, Reddy and co-workers (2006) conducted a randomized, double-blinded, placebo-controlled trial in which 60 postmenopausal women received gabapentin, 2400 mg/d; oral conjugated estrogen, 0.625 mg/d; or placebo for 12 weeks. The reductions in the hot flush composite scores for both estrogen (72 percent) and gabapentin (71 percent) were greater than that associated with placebo (54 percent). Headache, dizziness, and disorientation occurred, however, in almost 25 percent of the women treated with gabapentin.

Alpha-Methyldopa

At doses of 500 to 1000 mg/d methyldopa, an antihypertensive, has been shown to be twice as effective as placebo for the treatment of vasomotor symptoms. However, in studies evaluating its efficacy, side effects included dizziness, nausea, fatigue, and dry mouth (Fugate, 2004). Because of significant side effects with this drug and modest improvement in vasomotor symptoms, this drug is not recommended for this indication by the North American Menopause Society (2004).

Bellergal

Bellergal (Bellergal-S, no longer available in the U.S.) is a combined-preparation sedative that contains phenobarbital, ergotamine tartrate, and belladonna alkaloids (Loprinzi, 2005). In randomized double-blind studies, this agent showed either modest or no reduction in vasomotor symptoms compared with placebo. Moreover, in these studies, more than 30 percent of participants withdrew due to treatment ineffectiveness or side effects. Adverse reactions included dry mouth, dizziness, skin rash and drowsiness. Moreover, barbiturates are addictive and should not be recommended for long-term use. Because of its limited efficacy and significant side effects, this agent is not recommended for this indication (North American Menopause Society, 2004).

COMPLEMENTARY AND ALTERNATIVE MEDICINE

In 2005, out-of-pocket expenditures for alternative therapies were estimated at nearly $30 billion dollars, which was more than the out-of pocket expenditures for all physician services that year. By 2000, 34 percent of adults in the United States used complementary and alternative medicine (CAM). In 2002, 49 percent of women in the U.S. and Canada used CAM, and the trend seems to be increasing (Newton, 2002).

Phytoestrogens

Phytoestrogens (isoflavones) are plant-derived compounds that bind to estrogen receptors and have both estrogen agonist and antagonist properties. They are found in soy products and red clover. Small studies evaluating their effectiveness for the treatment of vasomotor symptoms have noted no efficacy or mixed results (Krebs, 2004).

Soy Products

Although the mechanisms of action of soy and dietary isoflavones are not fully understood, they appear to involve binding to the estrogen receptor. For this reason, one should not assume these dietary supplements are safe for women with estrogen-dependent cancers.

For treatment of hot flashes, data supporting isoflavone efficacy are mixed. Albertazzi and colleagues (1998) provided a pure dietary soy supplement that contained 40 mg of protein and 76 mg of isoflavones. In women using this supplement, a 45-percent reduction in vasomotor symptoms was noted compared with a 30-percent reduction in women receiving placebo. Cheng and associates (2007) provided 60 mg of isoflavones or placebo for 3 months to symptomatic women. They noted that isoflavone treatment reduced hot flashes by 57-percent. In contrast, in a double-blind clinical trial with breast cancer survivors, Quella and colleagues (2000) found no difference in vasomotor symptoms between women given soy tablets containing 150 mg of isoflavones per day and those administered placebo.

The effects of soy protein found in various food preparations are not bioequivalent. Even soy foods are not necessarily reliable sources of biologically active isoflavones. For example, the alcohol processing often used in the manufacture of tofu and soymilk removes the biologically active forms, the aglyconic isoflavones. Accordingly, soy food producers have recognized public interested in isoflavone supplements, and many indicate in their product labeling the amounts and forms of isoflavones found in the foodstuff.

Flaxseed

Flaxseed or flaxseed oil (*Linum usitatissimum*) is rich in α-linolenic acid, a form of omega-3 fatty acid. Also known as linseed, flaxseed is touted to reduce inflammation, bone turnover, heart disease, cancer, diabetes, and cholesterol levels. For perimenopausal women, it also is purported to protect against breast cancer, hot flushes, and mood disturbances. However, data regarding flaxseed efficacy for treatment of hot flushes are limited. Lewis and co-workers (2006) conducted a double-blinded, randomized controlled trial in which 87 women were assigned to one of three groups that daily ingested muffins that contained soy, flaxseed, or wheat. This study fund no significant difference in vasomotor symptoms among the three groups. In contrast, Lemay and associates (2002) found 40 g of flaxseed as effective as 0.625 mg of CEE for the treatment of mild menopausal symptoms in a randomized cross-over study comparing the two.

Red Clover

Trifolium pratense is a member of the legume family. It contains at least four estrogenic isoflavones, and is therefore marketed as a source of phytoestrogens. Several studies, however, have failed to demonstrate an effect over placebo in the treatment of menopausal symptoms (American College of Obstetricians and Gynecologists, 2004; Nelson, 2004). For example, a randomized controlled trial of 252 women studied hot flush frequency in women given red clover isoflavone extracts and placebo over 12 weeks. No significant change in hot flush frequency was reported between groups receiving isoflavones and those given placebo (Tice, 2003).

Dong Quai

Also translated as don kwai, dang gui, and tang kuei, this Chinese herbal medicine is derived from the root of *Angelica sinensis* , and is the most commonly prescribed Chinese herbal medicine for "female problems". Within traditional Chinese medicine (TCM) practice, dong quai is suggested to regulate and balance the menstrual cycle, strengthen the uterus, and enrich the blood. It is also said to exert estrogenic activity. Most herbal practitioners seem to agree it is contraindicated during pregnancy and lactation.

In 1997, Hirata and colleagues at Kaiser Permanente conducted a double-blinded controlled clinical trial using a daily dong quai dose of 4.5 g. Women using dong quai and those using placebo *both* reported a 25-percent reduction in hot flushes. Critics of the study have noted that the dose of dong quai was lower than that often used in TCM, and that dong quai is never employed as an isolated intervention. However, its benefit cannot be substantiated based on available evidence.

Dong quai is potentially toxic. It contains numerous coumarin-like derivatives and may cause excessive bleeding or interactions with other anticoagulants. This herbal agent also contains psoralens and is potentially photosensitizing, which increases concerns of sun exposureâ€“related skin cancers.

Black Cohosh

The root of the herb *Cimifuga racemosa* is also thought to have estrogenic properties, although the mechanism of action is unknown. In a randomized placebo-controlled trial in 85 women, it did not decrease the frequency of vasomotor symptoms compared with placebo (Krebs, 2004). Although few adverse effects have been reported, the long-term safety of these products is unknown. Two large NIH-sponsored studies with red clover and black cohosh are ongoing (www.clinicaltrials.gov .).

PHYTOPROGESTINS

Extracts, tablets, and creams derived from yams are claimed to be progesterone substitutes and are frequently touted as a natural source of dehydroepiandrosterone (DHEA). Sterol structures from the plant are used as precursors in the biosynthesis of progesterone, DHEA, and other steroids, but do not have inherent biological activity. Specifically, claims are made that the plant sterol *dioscorea* is converted into progesterone in the body and alleviates "estrogen dominance". Yam extracts are also purported to be effective for uterine cramps. However, there is no human biochemical pathway for bioconversion of dioscorea to progesterone or DHEA in vivo.

In contrast, Mexican yam extract is estrogenic, containing considerable *diosgenin* , an estrogen-like substance found in plants. Some estrogen effects might be expected from eating these yam species, but only if large quantities of raw yams are consumed. Yams from the grocery store generally are not the varieties known to contain significant amounts of dioscorea or diosgenin.

Based on the lack of bioavailability, the hormones in wild and Mexican yam would not be expected to have efficacy. Wild yam extracts are neither estrogenic nor progestational, and although many yam extract products contain no yam, some are laced with progesterone or medroxyprogesterone. Oral ingestion does not produce serum levels. There are no published reports demonstrating the effectiveness of wild yam cream for postmenopausal symptoms.

Vitamin E

In 125 women with a history of breast cancer, vitamin E produced a 25-percent reduction in hot flushes compared with a 22-percent reduction with placebo, a decrease of one hot flush per person per day (Barton, 1998).

ENVIRONMENTAL AND LIFESTYLE CHANGES

Practices that lower core body temperature such as using a fan, dressing in layers, and taking cool showers may temporarily help with night sweats and flushing. Relaxation techniques such as paced respiration can decrease symptoms. Meditation, smoking cessation, and weight loss may also be helpful, as are ingestion of cold foods and beverages.

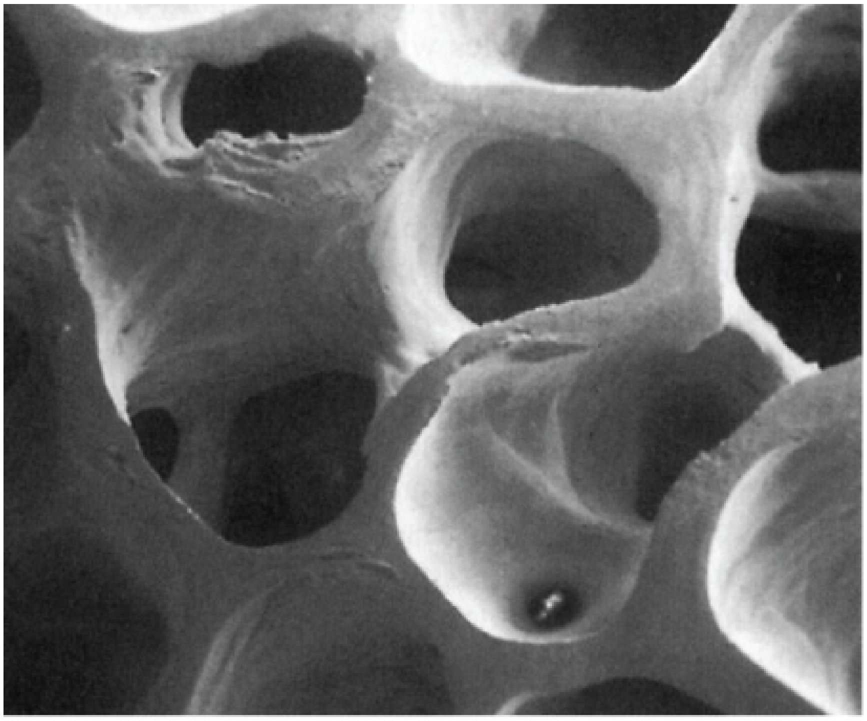
Therapies based on the interaction and the relaxation of the mind and the body for the treatment of menopausal symptoms have been shown to reduce the frequency of hot flushes. Irvin and co-workers (1996) randomized symptomatic menopausal women to relaxation, reading, or control groups. The relaxation group had significant reductions in hot flush intensity, tension, anxiety, and depression compared with the control group, which had no significant changes. Freedman and Woodward (1992) evaluated women with frequent hot flushes who were randomized to paced respiration, muscle relaxation, and placebo biofeedback. In the paced respiration group, there was a significant reduction in the hot flush frequency, although muscle relaxation and biofeedback showed no improvement. The proposed mechanism of action is decreased central sympathetic tone.

Treatment of Osteoporosis

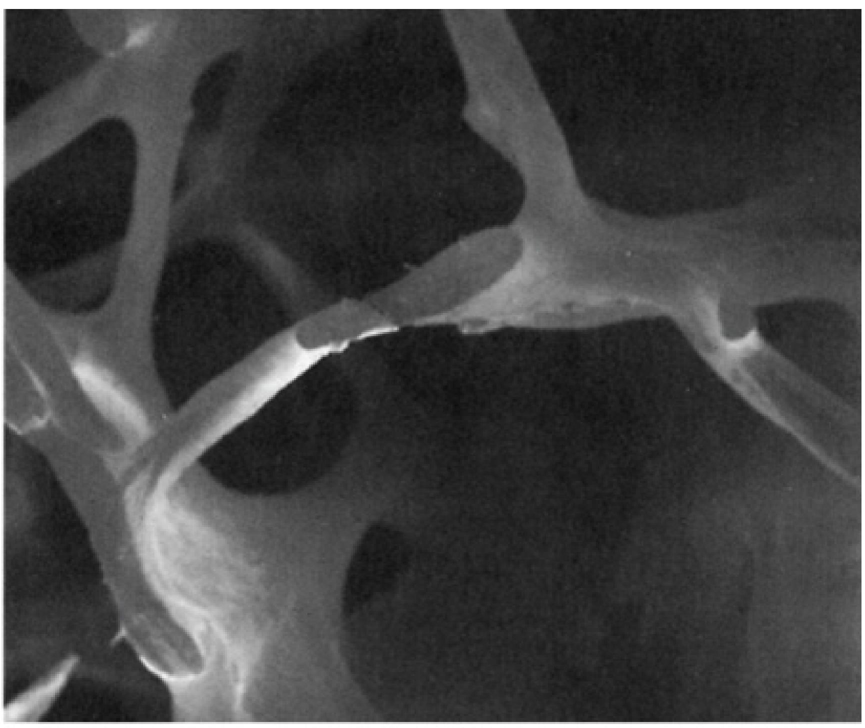
TREATMENT INDICATIONS

The primary goal of osteoporosis treatment is fracture prevention in women who have low bone mineral density (BMD) or additional risk factors for fracture (Fig. 22-1). Toward this end, therapy aims to stabilize or increase BMD. Treatment includes lifestyle changes and often pharmacologic therapy.

FIGURE 22-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Electron micrographs of tissue obtained from iliac crest biopsy. Normal bone architecture is seen in the biopsy from an individual with normal bone mineral density (**top**). Diminished bone architecture is seen in the biopsy from an individual with osteoporosis (**bottom**). *(From Dempster, 1986, with permission.)*

Several organizations offer guidelines for intervening with pharmacologic therapy (Table 22-4). The National Osteoporosis Foundation (NOF) and American Association of Clinical Endocrinologists (AACE) state that initiation of pharmacologic therapy should be considered for all postmenopausal women with T-scores less than â€“2.0 without other risk factors, or for those with T-scores less than â€“1.5 if other risk factors are present (see Table 21-6). Guidelines from the NOF also recommend initiating therapy to reduce fracture risk in women with a prior vertebral or hip fracture. Alternatively, the North American Menopause Society (NAMS) recommends starting therapy for: (1) all postmenopausal women with total hip or spine T-scores at or below â€“2.5, (2) for those with an osteoporotic vertebral fracture, and (3) all postmenopausal women with total hip or spine T-scores from â€“2.0 to â€“2.5 who have one or more additional risk factors for fracture.

Table 22-4 Thresholds for Initiation of Pharmacologic Therapy for Bone Fracture Prevention

	Without Risks (T-scores)	**With Risks (T-scores)**	**Prior Fracture**
NOF	<â€“2.0	<â€“1.5	Initiate therapy
AACE	<â€“2.0	<â€“1.5	N/A
NAMS	≤â€“2.5	â€“2.0 toâ€“2.5	Initiate therapy

AACE = American Association of Clinical Endocrinologists; N/A = not applicable; NAMS = North American Menopause Society; NOF = National Osteoporosis Foundation.

PHARMACOLOGIC CONSIDERATIONS

Drugs prescribed for fracture prevention attempt to restore and balance bone remodeling by reducing bone resorption or by stimulating bone formation. However, improvement in BMD with therapeutic intervention varies according to the composition of the bone. Therapies that prevent bone resorption will act most quickly on bone that has high trabecular content and rapid turnover, such as the vertebrae. In contrast, the impact of drug therapies on the hip may be delayed because the hip is composed of approximately 50 percent trabecular and 50 percent cortical bone (see Fig. 21-7).

Therapeutic options include hormone therapy (HT) for the prevention of osteoporosis, and bisphosphonates and selective estrogen receptor modulators (SERMs) for prevention *and* treatment. Additionally, calcitonin and an injectable recombinant human parathyroid hormone (PTH) have been approved for treatment. Of these, PTH is the first FDA-approved agent that works by stimulating bone formation rather than slowing bone resorption.

HORMONAL THERAPY

Estrogen and Progesterone Replacement

As estrogen levels decline, bone-remodeling rates increase and favor bone resorption over bone formation. Results from more than 50 randomized, placebo-controlled trials show HT reduces the rate of bone resorption and results in an increase in BMD (North American Menopause Society, 2002). The WHI demonstrated that therapy with estrogen plus progesterone prevents vertebral fractures in postmenopausal women not known to have osteoporosis (The Women's Health Initiative Steering Committee, 2004). This is the first study to show that an antiresorptives can reduce the incidence of hip fracture.

Unfortunately, this preventive effect is lost rapidly following discontinuation of HT (Barrett-Connor, 2003). Women participating in the National Osteoporosis Risk Assessment (NORA) trial who had discontinued estrogen therapy within the 5 years preceding the study demonstrated a significantly higher hip fracture risk than did women who had never received estrogen therapy (odds ratio 1.69; 95 percent CI 1.08 to 2.66).

Selective Estrogen Receptor Modulators

These oral drugs are nonhormonal compounds that bind to the estrogen receptor but induce different estrogenic responses in various tissues. For example, raloxifene (Evista, Eli Lilly) is the only selective estrogen receptor modulator (SERM) approved for the prevention and treatment of osteoporosis. It activates estrogen receptors in the bone but does not appear to activate those in the breast or uterus.

Raloxifene may be most appropriate for prevention and treatment of vertebral disease. For example, raloxifene prevented vertebral fractures in the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, which enrolled 7,705 postmenopausal women with osteoporosis. The beneficial effects of raloxifene, 60 mg/d, appeared rapidlyâ€"clinical vertebral fracture risk was reduced by 68 percent following the first year of therapy. In addition, this effect was sustained over time. At 4 years of treatment, dosages of 60 mg daily led to a 36-percent reduction in fractures, and 120 mg each day produced a 43-percent decline (Delmas, 2002; Ettinger, 1999). However, in the MORE trial, Ettinger reported that raloxifene therapy compared with placebo was not associated with significant reductions in nonvertebral fracture risks at 3 and 4 years.

In addition to its bone effects, raloxifene may protect against breast cancer, as suggested by observational studies of various clinical trials (Barrett-Connor, 2006). The incidence of breast cancer was evaluated as a secondary end point in the MORE trial. Investigators found that raloxifene was associated with a 65-percent relative risk reduction in all breast cancers. Of specific breast cancer subtypes, they noted a 90-percent reduction in estrogen receptorâ€"positive cancers, a 12-percent reduction in estrogen receptorâ€"negative breast cancers, and a 76-percent relative risk reduction in invasive breast cancer.

Raloxifene may not have the same increased cardiovascular risk profile as estrogen. In a MORE post hoc analysis, 4 years of raloxifene therapy had no adverse effect on cardiovascular events in the overall cohort. Advantageously, it did result in a significant 40-percent reduction in the incidence of cardiovascular events among a subgroup of women with increased cardiovascular risk (Barrett-Connor, 2002).

Of side effects, hot flushes are associated with raloxifene therapy, although the incidence is low (Cohen, 2000). Furthermore, raloxifene, 60 mg daily for 4 years, has been associated with an increased risk of thromboembolic events (RR 1.78, 95 percent CI 0.99 to 3.19). In one study, the relative risk associated with any dosage of raloxifene was 2.76 for deep vein thrombosis, 2.76 for pulmonary embolism, and 0.50 for retinal vein thrombosis (Delmas, 2002).

NONHORMONAL ANTIRESORPTIVE AGENTS

Currently there are two main types of nonhormonal pharmacologic agents: (1) those that primarily act by inhibiting resorption, termed *antiresorptives* , and (2) those that act by increasing bone formation, termed *anabolic agents* . Most of the bone-active agents currently available in the United States inhibit bone resorption. Estrogen and SERMs as well as bisphosphonates, calcitonin, and vitamin D each have anitresorptive properties. All have been shown to halt bone loss, and most also increase BMD.

Bisphosphonates

Three bisphosphonates are currently available and include alendronate (Fosamax, Merck&Co., Whitehouse Station, NJ), risedronate (Actonel, Proctor and Gamble Pharmaceuticals, Cincinnati, OH), and ibandronate (Boniva, Roche Pharmaceuticals, Nutley, NJ) (Table 22-5). A fourth bisphosphonate, zoledronate (Zometa, Novartis, East Hanover, NJ), is a potent bisphosphonate that has been approved as an intravenous infusion for malignancy-associated hypercalcemia treatment. Currently, it is undergoing a phase III clinical trial for the treatment of postmenopausal osteoporosis as an intravenous infusion once annually (Colon-Emeric, 2004; Lambrinoudaki, 2006).

Table 22-5 Agents Approved in the United States for the Management of Osteoporosis

Agents (Brand Name)	Dosage	FDA-Approved Indications
Bishosphonates		
Risedronate (Actonel)	5 mg orally daily 35 mg orally weekly	Prevention or treatment of postmenopausal osteoporosis
	5 mg orally daily	Treatment of glucocorticoid-induced osteoporosis
Alendronate (Fosamax)	5 mg orally daily 35 mg orally weekly	Prevention of postmenopausal osteoporosis
	10 mg orally daily	Treatment of postmenopausal osteoporosis
	70 mg orally weekly	
	5 mg orally daily (10 mg orally daily in postmen-opausal women not receiving estrogen)	Treatment of glucocorticoid-induced osteoporosis
Ibandronate (Boniva)	2.5 mg orally daily 150 mg orally monthly	Prevention or treatment of postmenopausal osteoporosis
Hormones		
Conjugated equine estrogen	0.625 mg orally daily	Prevention of postmenopausal osteoporosis
Various estrogen preparations	See Table 22-2	Prevention of postmenopausal osteoporosis
Recombinant human (PTH)		
Teriparatide (Forteo)	20 μgSC daily	Treatment of postmenopausal osteoporosis
SERM		
Raloxifene (Evista)	60 mg orally daily	Prevention or treatment of postmenopausal osteoporosis
Salmon calcitonin	200 IU intranasally daily (alternating nostrils daily)	Treatment of postmenopausal osteoporosis
	100 units SC or IM every other day	

FDA = Food and Drug Administration; IM = intramuscularly; PTH = parathyroid hormone: SC = subcutaneously; SERM = selective estrogen receptor modulator.

Modified from Zizic, 2004, with permission.

Bisphosphonates display poor bioavailability, and therefore should be taken on an empty stomach with adequate water for proper dissolution and absorption. In general, these agents have a favorable overall safety profile, and adverse event rates are comparable with placebo (Black, 1996; Harris, 1999). However, bisphosphonates may cause upper gastrointestinal (GI) inflammation, ulceration, and bleeding (Lanza, 2000). Thus, to aid delivery to the stomach and reduce the risk of esophageal irritation, dosing instructions should be reinforced with each patient. First, bisphosphonates should be taken in the morning with a full glass of water. During the 30 minutes following administration, no other food or beverages should be consumed. Finally, women must remain upright (sitting or standing) for at least 30 minutes after ingesting the drug.

In addition to GI effects, recently bisphosphonate use has been linked with osteonecrosis of the jaw (ONJ), especially following dental extractions (Marx, 2003; Srinivasan, 2007). Fortunately, this complication is rare with oral bisphosphonates (Ruggiero, 2004). More commonly, ONJ is seen with intravenous zoledronate use in those with malignancy-related bone disease (Woo, 2006).

Alendronate

This bisphosphonate is approved for the treatment and prevention of osteoporosis. Alendronate has been shown to reduce the risk of vertebral fractures in postmenopausal women with low BMD or osteoporosis, either with or without existing vertebral fractures (Table 22-6) (Black, 1996). Alendronate also reduces nonvertebral fracture risk in women with osteoporosis. Among women with osteoporosis who participated in the Fracture Intervention Trial (FIT), the risk of nonvertebral fractures was reduced by month 24. In addition, the effects of alendronate are sustained. For example, women who used alendronate for 5 years and then discontinued use for a subsequent 5 years had comparable nonvertebral fracture rates as women using the drug for 10 years (Black, 2006; Bone, 2004).

Table 22-6 Summary of Major Clinical Trials of Bisphosphonates in Women with Postmenopausal Osteoporosis

			Relative Reduction of Fracture Risk for Active Treatment versus Placebo	
Trial	**Inclusion Criteria (number of patients in the trial)**	**Dosage**	**Vertebral Fractures**	**Nonvertebral Fractures**
Risedronate (Actonel)				
VERT	Two or more vertebral fractures or one vertebral fracture and a T-score of â€“2.0 or lower (2,458)	5 mg daily	65% reduction after 1 yr ($p < .001$) 41% reduction after 3 yrs ($p = .003$)	NR 39% reduction after 3 yrs ($p = .02$)
VERT	Two or more vertebral fractures (1,226)	5 mg daily	61% reduction after 1 yr ($p = .001$) 49% reduction after 3 yrs ($p < .001$)	NR 33% reduction after 3 yrs ($p = .06$)
HIP	Osteoporosis or one or more risk factors for osteoporosis (9,331)	2.5 and 5 mg daily	NR	20% reduction after 3 yrs ($p = .03$)
Alendronate (Fosamax)				
FIT	Low femoral-neck BMD (4,432)	5 mg daily for 2 yrs followed by 10 mg daily for 2 yrs	44% reduction after 4 yrs ($p = .001$)	12% reduction after 4 yrs ($p = .13$)

FIT	Low femoral-neck BMD plus one or more clinical vertebral fractures (2,027)	5 mg daily for 2 yrs followed by 10 mg daily for 1 yr	47% reduction after 3 yrs (p <.001)	20% reduction after 3 yrs (p =.063)
Alendronate Phase III Osteoporosis Treatment Study	Osteoporosis (994)	5 or 10 mg daily for 3 yrs 20 mg daily for 2 yrs followed by 5 mg daily for 1 yr	48% reduction after 3 yrs, based on pooling of all data (p =.03)	21% reduction after 3 yrs (p values not reported; not significant)

BMD = bone mineral density; FIT = Fracture Intervention Trial; IHP = Hip Intervention Program; NR = not reported; VERT = Vertebral Efficacy with Risedronate Therapy.

Adapted from Zizic (2004), with permission.

Risedronate

This bisphosphonate is an effective agent in the prevention and treatment of postmenopausal osteoporosis. The strongest data supporting its efficacy stem from the Vertebral Efficacy with Risedronate Therapy (VERT) trials, conducted multinationally and also in North America. In the VERT multinational trial, Reginster and co-workers (2000) showed that risedronate reduced the risk of new vertebral fractures by 61 percent at 1 year and by 49 percent at 3 years of use. Moreover, both VERT trials found significant reductions in vertebral fractures as early as 6 months after initiation of risedronate therapy (Roux, 2004). Two extensions of these trials have provided evidence of sustained efficacy. The continuation of risedronate therapy for 2 additional years (5 years total) in the multinational VERT study was associated with a 59-percent reduction in new vertebral fractures compared with placebo.

Ibandronate

This newer bisphosphonate is approved for the prevention and treatment of postmenopausal osteoporosis. Ibandronate is an effective agent, and data from the Oral Ibandronate Osteoporosis Vertebral Fracture Trial in North America and Europe (BONE) trial showed that daily ibandronate lowered incident vertebral fracture risk by 62 percent (Chesnut, 2004). To improve compliance, this drug was evaluated as a once-monthly therapy. Once-monthly oral ibandronate is at least as effective and well tolerated as daily treatment (Miller, 2005; Reginster, 2006). Moreover, once-monthly administration may be more convenient and thereby improve compliance rates.

Calcitonin

The polypeptide hormone calcitonin decreases the rate of bone absorption by inhibiting resorptive activity in osteoclasts. Calcitonin is a protein and as such, oral administration leads to its digestion. For this reason, it is delivered as an injection or nasal spray (Fortical, Upsher-Smith, Minneapolis, MN; Miacalcin, Novartis, East Hanover, NJ) (see Table 22-5). Salmon calcitonin nasal spray has been associated with a reduction in vertebral fracture risk among postmenopausal women with osteoporosis. In the Prevent Recurrence of Osteoporotic Fractures (PROOF) study, calcitonin nasal spray, 200 IU administered daily for up to 5 years, reduced the risk of vertebral fractures by 33 percent compared with placebo. However, vertebral fracture reduction was not seen at lower (100 IU/d) or higher (400 IU/d) dosages (Chesnut, 2000). Moreover, in this study, calcitonin failed to produce significant reductions in nonvertebral fracture.

Some observational data suggest that calcitonin has an analgesic effect independent of its effect on bone (Hauselmann, 2000; Ofluoglu, 2007). This analgesic effect may make this agent particularly useful as an adjunct to other therapies for osteoporosis in women with painful, symptomatic fracture (Blau, 2003). Injectable or intranasal calcitonin is associated with an 8- to 10-percent incidence of nausea or gastric discomfort and a 10-percent incidence of local site reactions. These symptoms tend to decrease in severity with continued use. Nasal symptoms such as rhinitis occur in 3 percent of patients treated with intranasal calcitonin (Cranney, 2002).

PARATHYROID HORMONE

Recombinant parathyroid hormone (PTH 1â€“34), known as teriparatide, is given by subcutaneous injection and is approved by the FDA for the treatment of postmenopausal women with established osteoporosis, who are at high risk for fracture. Teriparatide (Forteo, Eli Lilly) increases osteoblast numbers and activity by recruiting new cells and reducing apoptosis of differentiated osteoblasts. At low daily doses of teriparatide, the anabolic effects of PTH predominate. This is in contrast to the catabolic effects generally associated with long-term, higher-dose, and chronic exposure to PTH.

Clinical studies indicate that teriparatide increases bone quality by increasing bone density, turnover, and size (Rubin, 2002). Moreover, improvements in microarchitectural elements are evident in both cancellous and cortical regions. In women with postmenopausal osteoporosis, teriparatide, 20 or 40 µg/day, administered for approximately 21 months, was associated with 65-percent and 69-percent reductions in vertebral fractures, and 35-percent and 40-percent reductions in nonvertebral fractures, respectively (Neer, 2001).

Similar findings were reported in a study of 52 women treated with concomitant teriparatide and HT compared with HT alone (Lindsay, 1997). In this study, at the end of 3 years, increases in spine, total hip, and total body BMD were 13.4 percent, 4.4 percent, and 3.7 percent, respectively, in the combined treatment group. The addition of alendronate to teriparatide, however, does not appear to enhance effects on BMD (Gasser, 2000). The effects of combination use of PTH with other bisphosphonates are not known.

In general, PTH is safe and well tolerated, although additional data from long-term studies are needed. The most frequent treatment-related adverse events in clinical trials of teriparatide were dizziness, leg cramps, nausea, and headache. Toxicity studies with rats have shown an increased risk of osteosarcoma, but as there are significant differences in bone metabolism between rats and humans, it is unlikely that the rat data are applicable to humans. However, a black box warning has been included on the product labeling in the United States, and use of teriparatide should be avoided by patients at increased risk for skeletal malignancy. Use for more than 2 years is not recommended due to the potential of side effects (Tashjian, 2002).

Other anabolic agents have been or are currently being studied for use in the treatment of osteoporosis and include fluoride, growth hormone, insulin-like growth factor-1, androgen, tibilone, strontium, and statins. Full-length PTH (PTH 1â€“84) is also currently under investigation (Greenspan, 2007; Rubin, 2002).

NONPHARMACOLOGIC THERAPY

Nonpharmacologic interventions are important cornerstones of osteoporosis prevention. They include dietary modifications, exercise programs, fall prevention strategies, and education.

Calcium

For bone maintenance, adequate daily calcium intake is essential. For women between 31 and 50 years, the recommended dietary reference intake (DRI) is 1,000 mg each day, whereas 1,200 mg is suggested for those 51 years and older (Institute of Medicine, 2002). Few meet these goals, and calcium deficiency is widespread. For example, more than

90 percent of women fail to take in enough calcium through their diets to meet DRIs put forth by the Food and Nutrition Board of the Institute of Medicine. Although poor calcium intake is observed at all ages, it appears to be most common among older individuals. Specifically, less than 1 percent of women 71 years or older actually meet recommended goals.

Calcium supplementation combined with vitamin D administration have been associated with reduced bone loss and decreased risk for fractures in a number of prospective studies (Chapuy, 1992; Dawson-Hughes, 1997; Larsen, 2004). However, supplementation must be continued long term for efficacy to be sustained.

Vitamin D

The DRI of vitamin D is 400 IU/d for those aged 51 to 70 years, and 600 IU/d for those older than 70. As with calcium, the prevalence of vitamin D deficiency is high, especially in the elderly. It leads to poor calcium absorption, secondary hyperparathyroidism, increased bone turnover, increased rates of bone loss, and if severe, impaired bone mineralization. In addition, vitamin D deficiency causes muscle weakness and is associated with an increase in rates of falls.

Vitamin D supplementation can reverse many of these effects and significantly reduce falls and hip fractures. Although a large study of patients aged 70 years and older failed to demonstrate a decrease in hip fractures using 400 IU/d of vitamin D for 3 years, other studies using approximately 800 IU/d of vitamin D have demonstrated fracture protection (Dawson-Hughes, 1997). These findings suggest that doses higher than the current DRI for vitamin D may be necessary for anti-fracture efficacy.

Diet

A relationship between protein intake and BMD has been reported, but a relationship with fractures has not been described. Using data from the Third National Health and Nutrition Examination Survey (NHANES III), Kerstetter and colleagues (2000) demonstrated a significant association between protein intake and total femur BMD among non-Hispanic white women aged 50 years and older. Moreover, protein supplementation (20 g/d) 5 times weekly for 6 months following hip fracture was associated with a 50-percent reduction in femoral bone loss at 1 year compared with placebo.

Although no specific recommendations regarding protein intake can be made based on the limited data available, it seems prudent for clinicians to ensure that their patients eat healthy diets that provide the daily DRI of protein. As put forth by the Institute of Medicine, diets should contain at least 46 g/d for women (Dawson-Hughes, 2002). There may be upper limits for desirable protein intake as well. Excess urinary calcium excretion has been observed in association with the large acid loads delivered by very-high-protein diets (Barzel, 1998). Although it is not yet proven, there is concern that these calcium losses may jeopardize bone strength.

Caffeine consumption does not appear to influence bone health in healthy postmenopausal women who maintain an adequate daily intake of calcium and vitamin D. However, one longitudinal study showed that even moderate amounts of caffeine (2 to 3 servings of coffee per day) may lead to bone loss in women with low calcium intake (less than 800 mg/d) (Harris, 1994).

Calcium reabsorption is directly proportional to sodium reabsorption in the renal tubule. Accordingly, increases in dietary sodium have been observed to cause increases in urinary calcium excretion and corresponding increases in biochemical markers of bone turnover. Specifically, a relationship between high sodium intake (more than 1,768 mg daily) and lower bone density has been described (Sellmeyer, 2002). This sodium effect appears to be independent of calcium intake and activity levels. As with caffeine, it would be considered practical for all women to moderate sodium intake as a precautionary measure until this relationship is fully understood.

Physical Activity

Small but statistically significant increases in BMD have been observed in postmenopausal women participating in exercise programs, including aerobic exercise and resistance training (heavy weight with few repetitions). A recent meta-analysis of 18 randomized, controlled trials concluded that aerobic, weight-bearing, and resistance exercise were all effective in increasing BMD of the spine. Of these, walking was observed to benefit BMD of both the spine and the hip, and aerobic exercise also increased wrist BMD (Bonaiuti, 2002).

Although an increase in bone density may occur, especially at the sites at which the exercise is directed, it is important to note that the benefits of exercise are likely to be due to factors other than changes in BMD (Carter, 2002). For example, an association between exercise and reduced falls has been reported. Improvements in balance, stronger muscles, better muscle tone, and stronger more flexible bone, all undoubtedly contribute to fracture reduction.

FALL-PREVENTION STRATEGIES

Falls are responsible for more than 90 percent of hip fractures (Carter, 2002). Sideways falls appear to be the most detrimental and were independently associated with hip fracture in a study by Greenspan and associates (1998). Therefore, fall prevention is essential for women with osteopenia or osteoporosis. Living conditions should be modified to minimize falls by reducing clutter and implementing nonslip tiles, rugs with nonskid backing, and night lights.

Hip protector padding was also initially thought to reduce hip fractures in elderly adults. However, a recent analysis of the Cochrane database by Parker (2003) indicates that the effectiveness of hip protectors may be less certain, and compliance remains low. Falls and fractures often occur at night, when women are likely to have taken off their hip protectors. This may result from the bulkiness of hip protectors, which are uncomfortable to wear while sleeping (van Schoor, 2003).

Treatment of Sex-Related Issues

DYSPAREUNIA

Estrogen Replacement

Low estradiol levels commonly lead to vaginal atrophy or dryness and subsequent dyspareunia. Data from the Yale Midlife Study showed a close relationship between serum estradiol level and sexual problems. In this study, significantly more women with estradiol levels less than 50 pg/mL reported vaginal dryness, dyspareunia, and pain compared with women whose estradiol levels were greater than 50 pg/mL (Sarrel, 1998). Prospective records of coital behavior and concomitant steroid analysis revealed that women with estradiol levels less than 35 pg/mL reported significant reductions in coital activity.

Estrogen replacement effectively reverses atrophic changes. Of these, vaginal atrophy and diminished vaginal mucosal elasticity, vaginal fluid secretion levels, blood flow, and sensorimotor responses are improved by either topical or systemic estrogen (Dennerstein, 2002). Moreover, a meta-analysis evaluated randomized, controlled trials from 1969 to 1995 investigators found, that compared with placebo, oral or vaginal estrogens significantly improved vaginal atrophy symptoms, dyspareunia, and vaginal pH (Cardozo, 1998). If oral and vaginal estrogens were compared, vaginal products had greater patient acceptance, lower systemic estradiol concentrations, yet significant improvement of dyspareunia and pH changes.

Of vaginal topical agents, available forms include creams, continuous-release rings, and tablets (Table 22-7). In comparing types during a 12-week study period, Ayton and colleagues (1996) found that a continuous low-dose estradiol-releasing vaginal ring (Estring, Pfizer, New York, NY) provided comparable relief to CEE vaginal cream used during 12 weeks. In addition, study patients found the vaginal ring significantly more acceptable than the cream. The ring is prescribed as a single unit. Each unit contains 2 mg of estradiol and is worn vaginally for 90 days and then replaced.

Table 22-7 Selected Estrogen Vaginal Preparations for the Treatment of Menopausal Vaginal Symptoms

Preparation	Generic Name	Brand Name	Dose
Vaginal cream	Conjugated estrogens	Premarin	0.625 mg per 2 g cream: 2 g daily for 2 weeks, then 1â€“2 g 2 to 3 times weekly
	17β-estradiol	Estrace	0.1 mg per 2 g cream: 2 g daily for 2 weeks, then 1â€“2 g 2 to 3 times weekly
Vaginal tablet	Estradiol hemihydrate	Vagifem	0.025 mg per tablet: 1 tablet daily for 2 weeks, then 1 tablet twice weekly
Vaginal ring	17α-estradiol	Estring	0.0075 μg daily (inserted every 90 days)

Most products listed in Table 22-2 for the treatment of menopausal hot flushes are also approved for the treatment of vaginal dryness.

From Grady, 2006, with permission.

Alternatively, a 25-μg 17β-estradiol tablet (Vagifem, Novo Nordisk Pharmaceuticals, Princeton, NJ) is available for vaginal application. One tablet is inserted daily for an initial 2 weeks of treatment, and is followed by twice-weekly application. These tablets and CEE vaginal cream have been found to be equivalent in relieving symptoms of atrophic vaginitis (Rioux, 2000). Advantageously, women using vaginal tablets had less endometrial proliferation or hyperplasia than those using cream. Additionally, tablets were rated significantly more favorable than the cream, and their use was associated with fewer patient withdrawals from the study.

Vaginal Lubricants and Moisturizers

A variety of water-soluble vaginal lubricants are available over the counter for treatment of vaginal dryness with coitus. Alternatively, a polycarbophil-based gel (Replens, Lil' Drug Store Products, Cedar Rapids, IA) offers a more sustained correction of vaginal dryness symptoms. This gel is an acidic hydrophilic insoluble polymer, which can hold water to act as a vaginal moisturizer. The polymer binds to the vaginal epithelium and is sloughed with epithelial layer turnover. In addition, the acidity of the gel helps to lower the vaginal pH to that found in premenopausal women.

LIBIDO

Estrogen Replacement

A randomized, double-blind crossover clinical trial showed significant positive effects of estrogen on mood and sexuality. A 12-month study of 49 women who had undergone oophorectomy reported a significant positive effect of estrogen on both mood and sexuality, apart from vaginal symptomatology. This 12-month trial had four 3-month arms with no washout period: (1) ethinyl estradiol (50 μg), (2) levonorgestrel (250 μg), (3) a combination of these two agents, and (4) placebo. Of these, ethinyl estradiol showed a significant positive effect on mood and sexual desire, enjoyment, and orgasmic frequency. There were no differences between groups in coital rate (Dennerstein, 2002).

Testosterone

Androgen replacement in women with hypoactive sexual desire disorder is a controversial topic. Although studies have documented an association between androgen replacement and improved sexual desire, large, quality trials with long-term follow-up are needed (Pauls, 2005). Shifren and colleagues (2000) demonstrated that women who underwent surgical menopause and who were subsequently treated with systemic estrogen had improved sexual function and psychological well-being if 300 μg of transdermal testosterone was concurrently delivered. However, there was a strong placebo response in this study, and many subjects had evidence of borderline-high androgen levels. Lobo and colleagues (2003) evaluated postmenopausal women to assess effects on hypoactive sexual desire disorder of 0.625 mg oral estrogen with or without 1.25 mg methyltestosterone. At a 16-week re-evaluation, therapy with methyltestosterone increased bioavailable testosterone and improved sexual interest and desire in most women.

Symptoms of androgen insufficiency include diminished sense of well-being, persistent fatigue, sexual function changes, and low levels of serum-free testosterone. Women with these findings may be offered replacement. Importantly, candidates should be counseled that most androgen replacement therapy is off-label and not U.S. FDA-approved. Moreover, most of the available data are based on short-term studies and long-term safety and efficacy are unknown (Braunstein, 2007). Therapy should be performed under close clinician supervision.

Early effects of androgen therapy include acne and hirsutism, with a recent study reporting a 3-percent increased rate of acne in testosterone-therapy groups (Lobo, 2003). Long-term side effects such as male pattern baldness, voice deepening, and clitoral hypertrophy are infrequent within normal androgen levels. Androgen therapy may adversely affect the lipid profile, and knowledge about long-term effects on cardiovascular risk is unknown (Davis, 2000).

Potential benefits of androgen include increased muscle mass and stimulation of bone formation as well as diminished hot flush frequency (Table 22-8) (Notelovitz, 2002). With therapy, levels of androgens, lipids, and liver enzymes initially should be performed at 1- to 2-month intervals. Restoration to the upper half of the normal androgen range is necessary to ensure a good therapeutic response (see Table 15-4). (Munarriz, 2002).

Table 22-8 Benefits of Testosterone Treatment for Women		
Indication	**Possible Benefit**	**Formulations**
Bone strength	Increase bone mineral density	Oral, supraphysiologic doses
Cognitive or psychological	Protective of memory, improved sense of well-being	Physiologic doses
Sexual dysfunction	Increase desire/interest, frequency Increase frequency, satisfaction, orgasm Increase desire, orgasm Increase frequency and pleasure	Oral Implants Intramuscular, supraphysiologic dose Transdermal

From Margo, 2006, with permission.

Currently the only FDA-approved testosterone preparation for women is methyltestosterone combined with esterified estrogen, suitable only for postmenopausal patients. A list of available testosterone preparations is shown in Table 22-9. Phase II trials have been carried out for a testosterone gel and testosterone patch, but FDA approval is delayed, waiting on longer-term safety and efficacy trials.

Table 22-9 Selected Androgens for Treatment of Menopausal Symptoms			
Brand Name	**Generic Name**	**Dosage**	**Manufacturer**
Oral androgen			
Halotestin	Fluoxymesterone	2 mg	Pfizer
Estrogen-androgen combinations			
Estratest	Esterified estrogens	1.25 mg	Solvay
	Methyltestosterone	2.5 mg	
Estratest HS	Esterified estrogens	0.625 mg	Solvay
	Methyltestosterone	1.25 mg	
Depo-Testadiol injection	Estradiol cypionate	2 mg	Pfizer
	Testosterone cypionate	50 mg	

Treatment of Depression

Major and minor depression are the two most prevalent forms of acute depressive illness in women (see Chaps. 13, Mood Disorder Prevalence). Although some controlled studies have shown improvement in mood with estrogen treatment, it is recommended that estrogen should not be used as a primary treatment for women with depression. First-line treatment for menopausal women presenting with depression would be a traditional antidepressant, such as a selective serotonin reuptake inhibitor (SSRI). However, treatment with estrogen for certain women who have mild to moderate depression may be selected as an alternative. Consideration may be given to those who fail to respond to a conventional first-line intervention, those who refuse to take psychotropic agents, or those who will begin HT for other acute menopausal symptoms and who could delay antidepressant therapy until determining whether estrogen treatment is sufficient.

Treatment of Skin Aging

As people age, their skin elasticity decreases and strong collagen fibers weaken. In addition, fatty tissue and collagen beneath the skin shrinks. As a result, the skin lays more loosely, and lines appear where the facial muscles attach to the skin's undersurface. Many factors play a role in the rate and degree of the aging. First and foremost is genetics. People with thin, dry, fair skin will realize signs earlier. In addition, overexposure to sunlight and excessive use of tobacco and alcohol accelerate skin aging. Thus, prevention of skin aging includes protection from ultraviolet (UV) light, avoidance of tobacco, and limitation of alcohol intake.

Skin is a hormonally sensitive structure, and both estrogen and androgen receptors have been localized to skin (Hasselquist, 1980; Schmidt, 1990). However, it is difficult to separate hormonal deficiency from chronological skin aging and age-related environmental insults such a smoking or photo-aging secondary to sun exposure.

The predominant evidence for an estrogen effect on skin has been derived from observational studies using various estrogen preparations with or without cyclic progestin. Thus, it is difficult to clearly separate the effects of estrogen from estrogen and progestin in many of the studies. There have been only two randomized, double-blinded, placebo-controlled trials that have examined the effects of estrogen therapy (ET) or hormone therapy on skin. Both trials suggest that ET increases dermis thickness, whereas HT can increase skin collagen fibers (Maheux, 1994; Sauerbronn, 2000). With few randomized studies addressing this topic, the American College of Obstetricians and Gynecologists (2004) states that "there is insufficient evidence to recommend estrogen treatment to increase skin thickness and collagen content and thereby decrease wrinkling in sun-exposed areas such as the face and forearms."

PREVENTIVE HEALTH CARE

Leading causes of morbidity and mortality for women older than 40 are found in Tables 22-10 and 22-11. Testing and prevention strategies are aimed at reducing the incidence and effects of these causes. In addition to testing, illness prevention requires patient education to enable women to play an active role in maintaining their own health. Through dialogue and counseling, clinicians and their actively participating patients can reap the benefits of preventive care. Although prevention recommendations for many of these causes of morbidity are reviewed in Chapter 1, a select few found commonly in older populations are discussed below.

Table 22-10 Leading Causes of Mortality in Older Women[a]
In those between 40 and 64 years:
Cancer
Heart disease
Cerebrovascular disease
Motor vehicle accident
Chronic obstructive pulmonary disease
Diabetes mellitus
In those older than 65 years:
Heart disease
Cancer
Cerebrovascular disease
Chronic obstructive pulmonary disease
Pneumonia and influenza
Diabetes mellitus
Motor vehicle accident

[a] For each age group, causes are listed by their descending frequency.

Table 22-11 Leading Causes of Morbidity for Women Older Than 40 Years[a]
Arthritis
Asthma
Back pain
Cancer
Cardiovascular disease
Chronic obstructive pulmonary disease
Depression

Prevention of Alzheimer Senile Dementia

Dementia is defined as a progressive decline in intellectual and cognitive function. Its causes can be categorized into three broad groups: (1) cases in which the brain is the target of a systemic illness; (2) primary structural causes such as tumor; and (3) primary degenerative diseases of the nervous system, such as senile dementia of the Alzheimer type (SDAT). It is estimated that up to 50 percent of women aged 85 years or older may suffer from senile dementia or SDAT.

Early signs of dementia may be subtle. In compensation, women commonly restrict their spheres of activity so that they continue to function well. Consequently, dementia may not become apparent until a woman attempts to function in a broader context. In these instances, she may become lost or show significant confusion.

Prevention or delay of senile dementia includes screening for and early treatment of reversible causes of dementia. Identification and treatment of systemic illness such as vitamin B12 deficiency, hypothyroidism, opportunistic infections such as cryptococcosis in immunocompromised hosts, and thiamine deficiency may reverse some forms of dementia. Central nervous system complications

of syphilis are rare. However, in those with acquired immune deficiency syndrome (AIDS), the frequency of tertiary syphilis has been rising.

The role of estrogen in the prevention of dementia is controversial. Several epidemiologic studies have suggested that HT prevents development of SDAT. Moreover, meta-analyses of observational studies found that HT was associated with a decreased risk of dementia (Yaffe, 1998). However, data from a large randomized double-blind placebo-controlled study found negative findings for a preventive role. Women enrolled in the Women's Health Initiative Memory Study (WHIMS), an ancillary study of the WHI, were noted to have increased rates of dementia compared with those given placebo (Shumaker, 2003, 2004). Unfortunately, these mixed findings leave unanswered questions regarding HT's efficacy in preventing dementia in postmenopausal women. Currently, HT is not recommended for this indication.

Prevention of Dental Disease Related to Menopause

Dental disease and tooth loss may be an indicator of osteoporosis. Maintenance of good dental hygiene and good bone mineral density will help retard dental disease associated with aging.

Prevention of Urogynecologic Disease

The development of pelvic organ prolapse and urinary incontinence is multifactorial. Thus, the effectiveness of preventive measures such as cesarean delivery, pelvic floor muscle training (Kegel exercises), and estrogen therapy is unclear. Estrogen receptors are found throughout the lower urinary and reproductive tracts. In these areas, hypoestrogenism is associated with collagen changes and diminished vascularity of the urethral subepithelial plexus. However, separating the effects of hypoestrogenism from aging in the genesis of pelvic organ prolapse and urinary incontinence is problematic and discussed in Chapters 23 and 24.

For a woman with obvious lower reproductive tract atrophic changes, a trial of vaginal estrogen treatment for urinary incontinence is reasonable. However, several studies evaluating effects of estrogen have noted either de novo development or worsening of incontinence in women using HT (Hendrix, 2005; Jackson, 2006). Accordingly, there is no current indication for the use of HT for the prevention of pelvic organ prolapse or incontinence.

DEFINITIONS

Urinary incontinence is defined as involuntary leakage of urine. In addition to the urethra, urine can also leak from an extra-urethral source, such as fistulas or congenital malformations of the lower urinary tract. Although a number of different forms of incontinence exist, this chapter will focus on the evaluation and management of stress and urge incontinence.

According to International Continence Society guidelines, urinary incontinence is a symptom, sign, as well as a condition (Abrams, 2002). For example, with *stress urinary incontinence* (SUI), a patient may complain of involuntary urine leakage on exertion or with sneezing or coughing. Concurrently with these events, involuntary leakage from the urethra synchronous with these events may be a documented sign noted by a provider. And as a condition, incontinence is objectively demonstrated during urodynamic evaluation if involuntary leakage of urine is seen with increased abdominal pressure and absence of detrusor contraction. Under these circumstances, when the symptom or sign of stress urinary incontinence is confirmed with objective testing, the term *urodynamic stress incontinence* (USI), formerly known as *genuine stress incontinence* is used.

With *urge urinary incontinence* , women have difficulty postponing urination urges and generally must promptly empty their bladder on cue and without delay. If urge urinary incontinence is objectively demonstrated by cystometric evaluation, the condition is known as *detrusor overactivity* (DO), formerly known as detrusor instability (DI). When both stress and urge components are present, it is called *mixed urinary incontinence.*

Functional incontinence occurs in situations in which a woman cannot reach a toilet in time because of physical, psychological, or mentation limitations. In most instances, this group would be continent if these issues were absent.

EPIDEMIOLOGY

In western societies, most epidemiologic studies indicate a prevalence of 25 to 55 percent. This wide range is attributed to the equally wide variety of investigative methodology, population characteristics, and definitions of incontinence. Moreover, current available data are further limited by the fact that most women do not seek medical attention for this condition (Hunskaar, 2000). It is estimated that only one in four women will seek medical advice for incontinence due to embarrassment, limited access to health care, or poor screening by health care providers (Hagstad, 1985).

Among ambulatory women with urinary incontinence, the most common condition is stress incontinence, which represents 29 to 75 percent of cases. Detrusor overactivity accounts for up to 33 percent of incontinence cases, whereas the remainder is attributable to mixed forms (Hunskaar, 2000).

Urinary incontinence can significantly impair the quality of life, leading to disrupted social relationships, psychological distress from embarrassment and frustration, hospitalizations due to skin breakdown and urinary tract infection, and nursing home admission. An incontinent elderly woman is 2.5 times more likely to be admitted to a nursing home than a continent one (Langa, 2002).

RISKS FOR URINARY INCONTINENCE

Age

The prevalence of incontinence appears to increase gradually during young adult life (Fig. 23-1). A broad peak is noted at middle age and then steadily increases after age 65 (Hannestad, 2000).

FIGURE 23-1

Prevalence of any (n = 6,170) and significant (n = 1,832) incontinence by age group *(From Hannestad, 2000, with permission.)*

The type of incontinence may differ by age, with some studies suggesting a higher prevalence of stress incontinence in women younger than 60 years and urge incontinence in older women (Hannestad, 2000). Not all studies confirm this finding, and the causes of these age-related trends are not clearly understood (Rortveit, 2003).

Race

Traditionally, Caucasian women are believed to have higher rates of urinary incontinence than women of other races. In contrast, urge incontinence is believed to be more prevalent among African-American women. However, these reports are not population based, and thus are not the best estimate of true racial differences. Most epidemiologic studies of urinary incontinence have been conducted in Caucasian populations. In addition, existing data on racial differences are largely based on small sample sizes (Bump, 1993). Of noted trends, it is not yet clear whether these differences are biologic, related to health care access, or affected by cultural expectations and symptom tolerance thresholds. Clearly, further study of non-Caucasian populations is needed.

Obesity

Several epidemiologic studies have shown that an increased body mass index (BMI) is a significant and independent risk factor for urinary incontinence of all types (Table 23-1). Evidence suggests that the prevalence of both urge and stress incontinence increases proportionately with BMI (Hannestad, 2003). Theoretically, the increase in intra-abdominal pressure that coincides with an increased BMI results in a proportionally higher intravesical pressure. This higher pressure overcomes urethral closing pressure and leads to incontinence (Bai, 2002). Deitel and co-workers (1988) reported a significant decline in the prevalence of stress urinary incontinence, from 61 to 11 percent, in 138 morbidly obese women following weight loss after bariatric surgery. Accordingly, as a greater proportion of our population becomes overweight and obese, we can expect to see an increase in the prevalence of urinary

incontinence in the United States (Flegal, 2002).

Smoking

Menopause

Studies have inconsistently demonstrated an increase in urinary dysfunction after a woman enters her postmenopausal years (Bump, 1998). In those with symptoms, separating hypoestrogenism effects from the effects of aging is difficult.

High-affinity estrogen receptors have been identified in the urethra, pubococcygeal muscle, and bladder trigone but are infrequently found elsewhere in the bladder (Iosif, 1981). It is believed that hypoestrogenic-related collagen changes and reductions in urethral vascularity and volume of skeletal muscle collectively may contribute to impaired urethral function via a decreased resting urethral pressure (Carlile, 1988). Moreover, estrogen deficiency with resulting urogenital atrophy is thought responsible in part for urinary sensory symptoms following menopause (Raz, 1993). Despite this current evidence that estrogen plays a role in normal urinary function, it is less clear whether estrogen therapy is useful in the treatment or prevention of incontinence (Estrogen Replacement) (Fantl, 1994, 1996).

Childbirth and Pregnancy

Many studies reveal a higher prevalence of urinary incontinence in parous women compared with nulliparous women. The effects of childbirth on incontinence may result from direct injury to pelvic muscles and connective tissue attachments. In addition, nerve damage from trauma or stretch may result in pelvic muscle dysfunction (Snooks, 1986). Specifically, a higher rate of prolonged pudendal nerve motor latency after delivery has been demonstrated in women with incontinence compared with that of asymptomatic women.

Smoking and Chronic Lung Disease

Two large epidemiologic studies have demonstrated a significant increase in the risk for urinary incontinence in women older than

60 years with chronic obstructive pulmonary disease (Brown, 1996; Diokno, 1990). Similarly, cigarette smoking is identified as an independent risk factor for urinary incontinence in several studies. In one of these studies, both current and former smokers were noted to have a two- to threefold risk of incontinence compared with nonsmokers (Bump, 1992). Theoretically, persistently increased intra-abdominal pressures are generated from a smoker's chronic cough, and collagen synthesis is diminished by the anti- estrogenic effect of smoking.

Hysterectomy

Studies have inconsistently shown that hysterectomy is a risk factor for developing urinary incontinence. Those that show an association are retrospective, lack appropriate control groups, and are often based solely on subjective data (Bump, 1998). In contrast, studies that include pre- and postoperative urodynamic testing reveal clinically insignificant changes in bladder function. Moreover, evidence does not support avoidance of clinically indicated hysterectomy nor the performance of supracervical hysterectomy as measures to prevent urinary incontinence (Vervest, 1989; Wake, 1980).

PATHOPHYSIOLOGY

Continence

The bladder is a storage organ of urine with the capacity to accommodate large increases in urine volume with minimal or no increases in intravesical pressure. The ability to maintain urine storage with convenient and socially acceptable voluntary emptying is *continence.*

Continence requires the complex coordination of multiple components that include muscle contraction and relaxation, appropriate connective tissue support, and integrated innervation of and communication between these structures. Simplistically, during filling, urethral contraction is coordinated with bladder relaxation and urine is stored. In turn, during voiding, the urethra relaxes and the bladder contracts. These mechanisms can be challenged by uninhibited detrusor contractions, marked increases in intra-abdominal pressures, and changes to the various anatomic components of the continence mechanism.

Bladder Filling

BLADDER ANATOMY

The bladder wall is multilayered and contains mucosal, submucosal, muscular, and adventitial layers (Fig. 23-2). The bladder mucosa is comprised of a transitional cell epithelium, supported by a lamina propria. With small bladder volumes, the mucosa is thrown into convoluted folds. However, with bladder filling, it is stretched and thinned. The bladder epithelium, termed *uroepithelium* , is comprised of three distinct cell layers. The most superficial is the umbrella cell layer, and its impermeability is thought to create the primary urine-plasma barrier.

FIGURE 23-2

Bladder anatomy. **A.** Anteroposterior view of bladder anatomy. Inset: The bladder wall contains mucosal, submucosal, muscular, and adventitial layers. **B.** Photomicrograph of the bladder wall. The mucosa of an empty bladder is thrown into convoluted folds or rugae. The plexiform arrangement of muscle fibers of the detrusor muscle cause difficulty in defining its three distinct layers. **C.** Shapes and position of the bladder when empty and full. *(From McKinley, 2006, with permission.)*

In addition to its three cellular layers, the uroepithelium is covered on its cavity surface by a glycosaminoglycan (GAG) layer. This

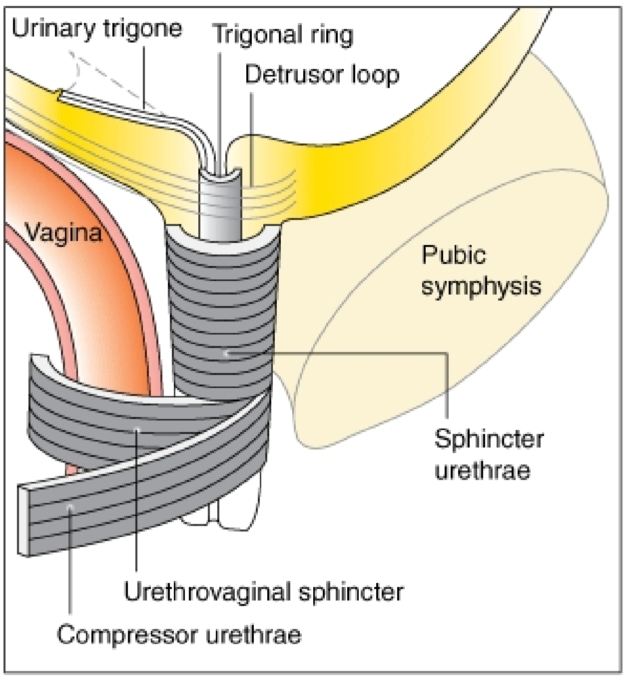
GAG layer may prohibit bacterial adherence and prevents urothelial damage by acting as a protective barrier. Specifically, theories describe that this layer of carbohydrate polymers may be defective in patients with interstitial cystitis (see Chap. 11, Interstitial Cystitis).

The muscular layer, termed the detrusor muscle, is composed of three smooth muscle layers arranged in a plexiform fashion. This unique plexiform arrangement allows for rapid multidimensional expansion during bladder filling and is a key component to the bladder's ability to accommodate large volumes of urine.

UROGENITAL SPHINCTER

As the bladder fills, synchronized contraction of the striated urogenital sphincter is integral to continence. Components of this sphincter include: (1) the *sphincter urethrae* (SU), (2) the *urethrovaginal sphincter* (UVS), and (3) the *compressor urethrae* (CU) (Fig. 23-3). The sphincter urethrae is striated muscle and wraps circumferentially around the urethra. In comparison, the UVS and CU are striated muscle bands that arch ventrally over the urethra and insert into the fibromuscular tissue of the anterior vaginal wall.

FIGURE 23-3



Striated urogenital sphincter anatomy. *(From DeLancey, 2003, with permission.)*

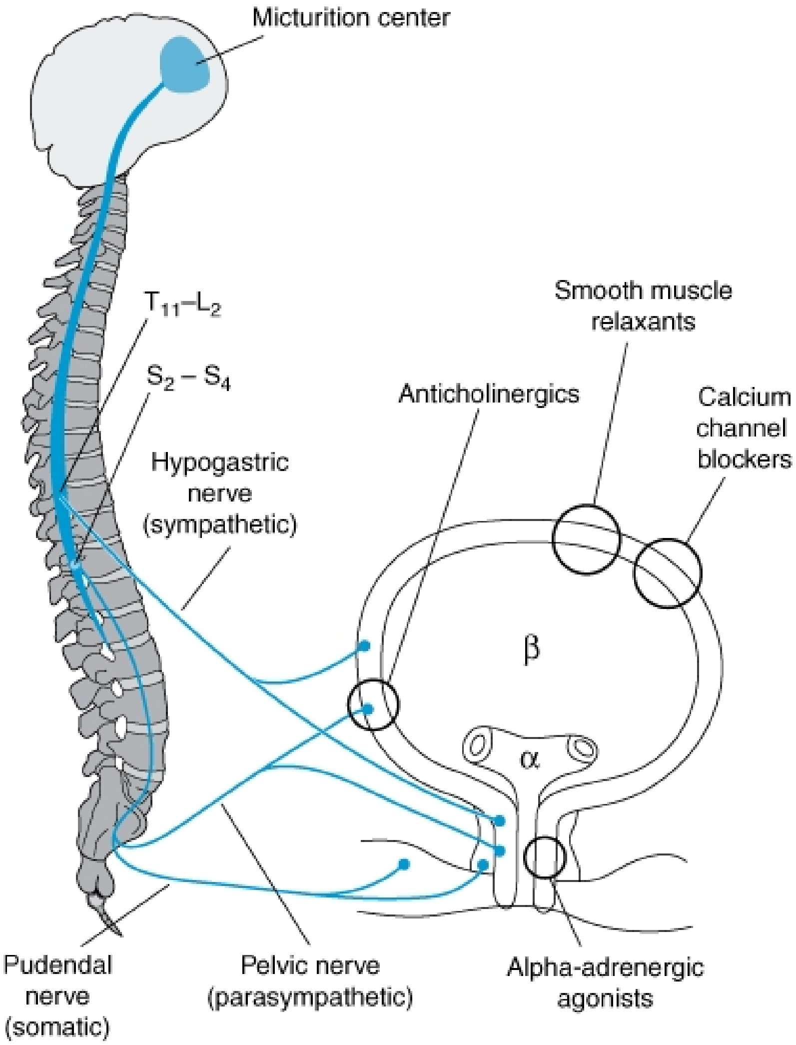
These three muscles function as a single unit and contract effectively to close the urethra. Contraction of these muscles circumferentially constricts the upper two thirds of the urethra and laterally compresses the lower one third. The sphincter urethrae is predominantly composed of slow twitch fibers and remains tonically contracted, contributing substantially to continence at rest. In contrast, the UVS and CU are comprised of fast twitch muscle fibers, which allow brisk contraction and urethra lumen closure when continence is challenged by sudden increases in intra-abdominal pressure.

INNERVATION IMPORTANT TO STORAGE

The striated urogenital sphincter muscles receive motor innervation through the pudendal nerve (Fig. 23-4). These somatic nerve fibers control the voluntary striated muscle of this sphincter. Thus, pudendal neuropathy, which may follow prolonged labor, can affect normal functioning of these muscles. Additionally, prior pelvic surgery or pelvic radiotherapy may damage nerves,

vasculature, and soft tissue. This can lead to ineffective urogenital sphincter action and contribute to incontinence.

FIGURE 23-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

As the bladder fills, sensory afferent signals are carried through the pelvic and hypogastric nerves to the spinal cord, where they are relayed to the pontine micturition center via the lateral spinothalamic tracts and dorsal columns. Sympathetic stimulation transmitted through the hypogastric nerve maintains smooth muscleâ€"based activity of the urethral sphincter and aids in detrusor relaxation to promote urine storage. Concurrently, somatic efferent signals to the striated muscle of the pelvic floor transferred through the pudendal nerve provide voluntary urethral sphincter activity and rapid augmentation of urethral resistance in response to sudden increases in bladder pressure. As afferent signaling increases in intensity with bladder filling, a threshold of consciousness is reached, at which point a socially appropriate opportunity to void is sought. At that point, signaling from the pontine micturition center to the sacral cord travels through the reticulospinal and corticospinal tracts. Parasympathetic cholinergic stimulation of the detrusor and reflex relaxation of the striated muscle of the pelvic floor follows and urination ensues. Sites of pharmacologic agent action are shown by circles. *(From Sourander, 1990, with permission.)*

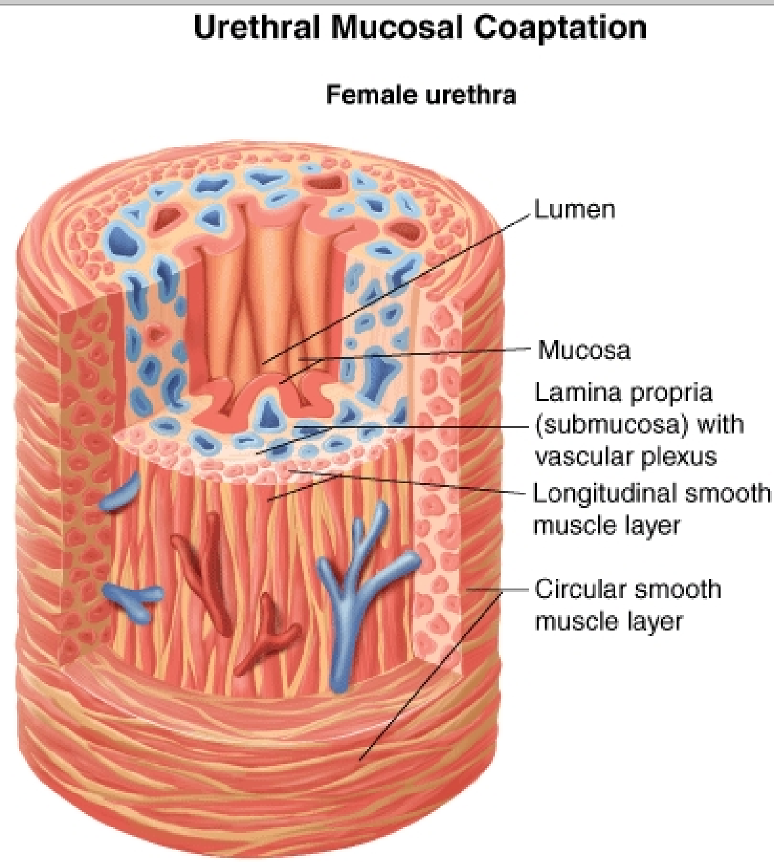
Sympathetic fibers are carried through the hypogastric nerve plexus and communicate with α- and β-receptors within the bladder and urethra (see Fig. 23-4). β-Adrenergic receptor stimulation in the bladder dome results in smooth muscle relaxation and assists with urine storage. In contrast, α_1 receptors predominate in the bladder base and urethra. Alpha-adrenergic receptors are stimulated by norepinephrine, which results in a cascade of events that preferentially leads to urethral contraction and aids urine storage and continence. These effects of alpha stimulation underlie the treatment of stress urinary incontinence with imipramine, a

tricyclic antidepressant with adrenergic agonist properties (Medications).

URETHRAL COAPTATION

One key requirement in maintaining continence is adequate urethral mucosa coaptation. As previously described, the uroepithelium is supported by a connective tissue layer, which is thrown into deep folds or plications. A rich capillary network runs within its subepithelial layer. This vascular network aids in urethral mucosal approximation, also termed *coaptation,* by acting like an inflatable cushion (Fig. 23-5). In women who are hypoestrogenic, this submucosal vasculature plexus is less prominent. In part, hormone replacement targets this diminished vascularity and enhances coaptation to improve continence.

FIGURE 23-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Drawing of urethral anatomy. Urethral coaptation results in part from filling of the rich subepithelial vascular plexus. The urethra contains smooth muscle layers. These are distinct from the striated urogenital sphincter (not illustrated). *(Redrawn from Craig, 1995.)*

Bladder Emptying

INNERVATION RELATED TO VOIDING

When an appropriate time for bladder emptying arises, sympathetic stimulation is reduced and parasympathetic stimulation is triggered. Specifically, neural impulses carried in the pelvic nerves stimulate acetylcholine release and lead to detrusor muscle contraction (see Fig. 23-4). Concurrent to detrusor stimulation, acetylcholine stimulates receptors in the urethra and leads to outlet relaxation for voiding.

Within the parasympathetic system, acetylcholine receptors are broadly defined as muscarinic and nicotinic. The bladder is densely supplied with muscarinic receptors. Of the muscarinic receptors, five glycoproteins designated M_1 through M_5 , have been identified.

The M_2 and M_3 receptor subtypes have been identified as mainly responsible for detrusor smooth muscle contraction. Thus, treatment with muscarinic antagonist medications blunts detrusor contraction to improve continence. Specifically, continence drugs that target only the M_3 receptor maximize drug efficacy yet minimize activation of other muscarinic receptors and drug side effects.

MUSCULAR ACTIVITY WITH VOIDING

Smooth muscle cells within the detrusor fuse with one another so that low-resistance electrical pathways exist from one muscle cell to the next. Thus, action potentials can spread quickly throughout the detrusor muscle to cause rapid contraction of the entire bladder. In addition, the plexiform arrangement of bladder detrusor fibers allows multidirectional contraction and is ideally suited for rapid concentric contraction during bladder emptying.

During voiding, all components of the striated urogenital sphincter relax. Importantly, bladder contraction and sphincter relaxation must be coordinated for effective voiding. Occasionally, tonic contraction of the detrusor may be dyssynchronous with urethral relaxation. With detrusor sphincter dyssynergia, the urethra fails to relax during detrusor contraction and retention ensues. Occasionally, women with this condition may be treated with pharmacologic agents such as muscle relaxants. These drugs purportedly relax the urethral sphincter and levator ani muscles to improve coordinated voiding.

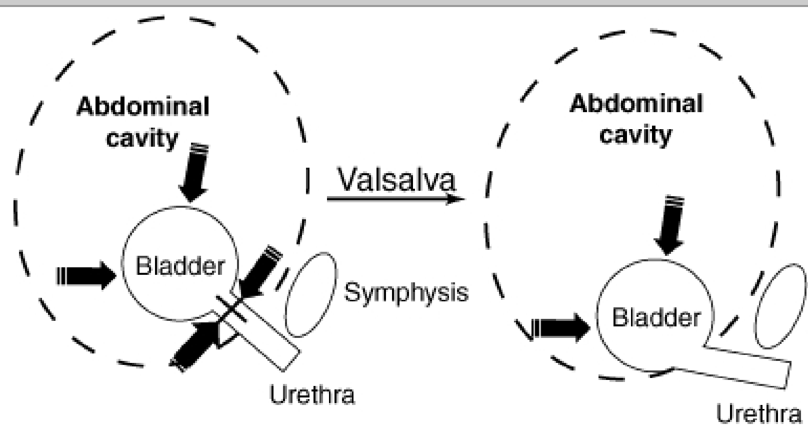
Continence Theories

Theories on continence are abundant and involve concepts relating to pressure transmission, anatomic support, and urethral integrity. These vary in the amount of supporting scientific evidence for each theory. However, currently these serve as the underpinning for current urogynecologic treatment. Precisely dissecting the mechanism behind incontinence is difficult, thus artificial separation of etiology may provide little value to the general practitioner. Thus, simplistically, continence can be conceptualized in terms of urethral support and urethral integrity.

Pressure Transmission

In an ideally supported urogenital tract, increases in intra-abdominal pressure are equally transmitted to the bladder, bladder base, and urethra. In women who are continent, increases in downward-directed pressure from cough, laugh, sneeze, and Valsalva maneuver are countered by supportive tissue tone provided by the levator ani muscle and vaginal connective tissue (Fig. 23-6). In those with a weakened supportive "backboard", however, downward forces are not countered. This leads to funneling of the urethrovesical junction, a patent urethra, and in turn, urine leakage. This mechanistic theory is the basis for surgical re-establishment of this support. Procedures such as Burch colposuspension are used to recreate this support (see Section 42-2, Burch Colposuspension).

FIGURE 23-6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Drawing describes the pressure transmission theory. In women with normal support, increases in intra-abdominal pressure are equally distributed to contralateral sides of the bladder and urethra. In those with poor urethral support, increases in intra-abdominal pressure alter the urethrovesical angle and continence is lost.

Urethral Support

Urethral support is integral to continence. This support is derived from: (1) ligaments along the lateral aspects of the urethra, termed the pubourethral ligaments; (2) the vagina and its lateral fascial condensation; (3) the arcus tendinous fascia pelvic; and (4) levator ani muscles (see Fig. 38-11). With loss of urethral support, the urethra's ability to close against a firm supportive backboard is diminished. This results in reduced urethral closing pressures and an inability to resist increases in bladder pressure. Thus, continence is lost.

RESTORATION OF URETHRAL SUPPORT

Therapies to improve urethral support include pelvic floor muscle training (Kegel exercises) and vaginal pessary use (Pelvic Floor Strengthening Exercises). Again, urethropexy procedures such as Burch and Marshall-Marchetti-Kranz (MMK) colposuspensions attempt to re-establish this anatomic support of the urethrovesical junction and proximal urethra.

Urethral Integrity

FACTORS AFFECTING INTEGRITY

The urethra maintains continence through the combination of urethral mucosal coaptation, the viscoelastic properties of the urethral epithelium, the underlying urethral vascular plexus, and contraction of appropriate surrounding musculature (see Fig. 23-5). Defects in any of these components may lead to urine leakage.

For example, prior surgery in the retropubic space may cause denervation and scarring of the urethra and its supporting tissue. These effects subsequently prevent urethral closure and lead to incontinence. This resulting urethral state is termed *intrinsic sphincteric defect* (ISD), and colloquially is referred to as a "lead pipe" urethra. With ISD, denervation and/or devascularization of the urethra are common underlying findings. Specific causes are varied and include prior pelvic reconstructive surgeries, prior pelvic radiotherapy, hypoestrogenism, diabetic neuropathy, and neuronal degenerative diseases. In women with atrophic lower genital tracts, vascular changes within the plexus surrounding the urethra lead to poor coaptation and greater risks of incontinence. Accordingly, estrogen replacement therapy targets this vascular system and often leads to greater mucosal coaptation and improved continence.

Trauma associated with childbirth may alter lower urinary tract innervation and may lead to immediate and potentially persistent incontinence. In these situations, nerve dysfunction following birth trauma to the urethra leads to defective sphincter function. In addition, childbirth also commonly injures fascial support to the urethra. This clinical example highlights the intimate relationship between urethral support and urethral integrity.

RESTORATION OF URETHRAL INTEGRITY

Treatment directed at restoring urethral integrity includes transurethral injection of bulking agents, surgical sling procedures, and pelvic floor muscle strengthening. Bulking agents such as collagen are placed below the urethral muscularis at the level of the urethrovesical junction to elevate the epithelium and promote coaptation. Alternatively, the partially obstructive nature of pubovaginal sling procedures enhances urethral integrity. Lastly, because the urethra exits through the urogenital hiatus, conditioning of the levator ani muscles with pelvic floor muscle training can bolster urethral integrity. These muscles can be contracted around the urethra when continence is challenged by sudden increases in intra-abdominal pressures.

DIAGNOSIS

History

SYMPTOM CLUSTERING

To methodically quantify symptoms for research purposes and compare outcomes between different treatments for incontinence,

investigators have created a variety of validated patient questionnaires to evaluate treatment efficacy (Kelleher, 1997; Patrick 1999; Wagner 1996). Many of these tools are lengthy and may be impractical for general clinical practice. More simply, assessment of incontinence may begin with a description of urinary symptoms. This inventory may be collected through direct conversation, but more commonly begins with completion of a patient questionnaire as shown in Table 23-2.

Table 23-2 Review of Systems for Women with Urinary Incontinence

Leak with stress	Y/N
Leak with urge	Y/N
Leak with position changes	Y/N
Leak with exercise	Y/N
Leak with intercourse/orgasm	Y/N
Unconscious leakage	Y/N
Duration of symptoms______wk______mo______yr	
Leaks per______day______wk______mo	
Pads per day______Type of pads______	
Voids daytime:_________	
Voids nighttime:__________	
Constipation	Y/N
Self Rx with__________________________________	
BMs_________/day_________/week	
Anal incontinence	Y/N
Duration__________mo__________yr	
Flatus__________/wk__________/mo	
Liquid__________/wk__________/mo	
Stool__________/wk__________/mo	
Digital decompression of bowel	Y/N
Digital decompression of bladder	Y/N
Postvoid dribble	Y/N
Feeling of incomplete emptying	Y/N
Recurrent UTI___________/yr	

Void with Valsalva	Y/N
Urine stream: strong/normal/weak	
Childhood enuresis	Y/N
Frequency	Y/N
Urgency	Y/N
Dysuria	Y/N
Hematuria	Y/N
Back pain	Y/N
Pelvic pressure/Bulge	Y/N
Dyspareunia	Y/N
Rectal bleeding	Y/N
Does heavy lifting	Y/N
Interfers w/lifestyle or quality of life	Y/N

During inquiry, the number of voids and pads used per day, type of pad, frequency of pad changing, and the degree of pad saturation are important considerations. Although these specifics alone may not establish the exact type of incontinence, they do provide information regarding symptom severity and its effects on patient activities. Obviously, if a woman's symptoms do not diminish her quality of life, then simple observation is reasonable. Conversely, those with disruptive symptoms warrant further evaluation.

Specific to incontinence, information that describes the circumstances in which leakage occurs and specific maneuvers that incite or provoke leakage should be sought. With stress urinary incontinence (SUI), provokers may include increases in intra-abdominal pressure such as coughing, sneezing, Valsalva maneuver, or thrusting during intercourse (Table 23-3). Alternatively, women with urge incontinence may describe a loss of urine after sensations of urgency, which typically cannot be suppressed.

Table 23-3 Symptom Comparison of Women with Stress or Urge Incontinence

Symptom	**Urge Incontinence**	**Stress Incontinence**
Urgency	Yes	No
Frequency with urgency	Yes	No
Urine leakage with increased intra-abdominal pressures	No	Yes
Amount of urinary leakage with each incontinence episode	Large (if present)	Small
Ability to reach the toilet in time following an urge to void	Often no	Yes
Waking to void at night	Usually	Seldom

Overflow incontinence was a term used in the past to refer to women who had an inability to empty their bladder and had episodes

of incontinence associated with urgency. Currently, however, this is considered by most to reflect another presentation of urge urinary incontinence. These women often note a sudden large loss of urine that is preceded by an inability to empty their bladder.

During questioning, symptoms typically cluster into those most frequently seen with SUI or with urge urinary incontinence. Alternatively, a significant overlap of complaints may reflect co-existent SUI and urge urinary incontinence, that is, mixed urinary incontinence. For these reasons, pattern identification is helpful and may direct diagnostic testing and guide initial empiric therapy.

VOIDING DIARY

Typically, patients may not have an entirely accurate recollection of their own voiding habits. Accordingly, to obtain a thorough record, a woman should complete a urinary diary (Fig. 23-7). With this, women are instructed to record for 3 days the volumes of each oral fluid intake, volumes of urine with each void, episodes of urinary leakage, and provokers of incontinence episodes. During each 24-hour period, women should also record times of sleep and awakening. This enables an accurate description of voluntary nocturnal voiding patterns as well as enuresis. Although 5 to 7 days of documentation is desirable, 3 days will suffice in determining the general trend of incontinence. Furthermore, realistically, most are typically not compliant for more than 3 days.

FIGURE 23-7

Bladder Diary

Please record the time and amount of your oral intake, urine output, urine leakage, and pad changes FOR 3 DAYS

Time	Oral Intake	Voided Urine	Urine Leakage or Pad Change

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Example of a urinary diary.

The historical information gained from a voiding/urinary diary is a valuable diagnostic tool. Moreover, this method of quantifying incontinence can also be used again later to provide an assessment of treatment efficacy.

URINARY SYMPTOMS

Urinary Frequency

Most women void eight times per day or less. Without a history that reflects increased fluid intake, increased voiding may indicate urge incontinence, urinary tract infection, calculi, or urethral pathology, and should prompt additional evaluation. In addition, urinary frequency is commonly associated with interstitial cystitis (IC). In women with IC, the number of voids may commonly exceed 20 per day. In women with urge incontinence or in those with systemic fluid management disorders such as congestive heart failure, nocturia may be noted. In the latter case, treatment of the underlying condition frequently leads to symptom improvement or cure.

Urinary Retention

It is important to determine if the patient adequately empties her bladder. Often incomplete emptying can result in incontinence associated with either stress or urgency. The term overflow incontinence is no longer used.

Other Urinary Symptoms

The volume of urine lost with each episode may also provide diagnostic clues. Large volumes are typically lost following the spontaneous detrusor contractions associated with urge urinary incontinence and may often involve loss of the entire bladder volume. In contrast, women with SUI usually describe smaller volumes lost. Moreover, these women often are able to contract the levator ani muscles to temporarily stop their urine stream.

Postvoid dribbling is classically associated with urethral diverticulum, which may often be mistaken for urinary incontinence (see Chap. 26, Patient Signs and Symptoms). Hematuria, although a common sign of UTI, may also indicate underlying malignancy and can cause irritative voiding symptoms.

The onset of symptoms may also provide information regarding etiology and treatment. For example, onset of symptoms with the menopause may suggest that a hypoestrogenic state underlies incontinence. These patients may benefit from estrogen replacement. In contrast, symptoms after hysterectomy or childbirth may reflect changes in tissue support or innervation.

PAST MEDICAL HISTORY

In addition to specific details describing urinary symptoms, other medical factors may be associated with incontinence. Obstetric trauma may be associated with damage to pelvic floor support, which may lead to SUI. For this reason, information describing a prolonged labor, operative vaginal delivery, macrosomia, postpartum catheterization for urinary retention, and increased parity may be valuable. Prior radiation therapy for malignancy may lead to irritative voiding symptoms or intrinsic sphincteric deficiency, which predisposes to SUI. Finally, a detailed medication inventory should be collected. Pertinent drugs may include estrogen, α-adrenergic agonists, and diuretics (Table 23-4).

Table 23-4 Medications that May Contribute to Incontinence

Medication	Examples	Mechanism	Effect
Alcohol	Beer, wine, hard liquor	Diuretic effect, sedation, immobility	Polyuria, frequency
α-adrenergic agonists	Decongestants, diet pills	IUS contraction	Urinary retention
α-adrenergic blockers	Prazosin, terazosin, doxazosin	IUS relaxation	Urinary leakage
Anticholinergic agents		Inhibit bladder contraction, sedation, fecal impaction	Urinary retention and/or functional incontinence
Antihistamines	Diphenhydramine, scopolamine, dimenhydrinate		
Antipsychotics	Thioridazine, chlorpromazine, haloperidol		
Antiparkinsonians	Trihexyphenidyl, benztropine mesylate		
Miscellaneous	Dicyclomine, disopyramide		
Skeletal muscle relaxants	Orphenadrine, cyclobenzaprine		
Tricyclic antidepressants	Amitriptyline, imipramine, nortriptyline, doxepin		
Angiotensin-converting enzyme (ACE) inhibitors	Enalapril, captopril, lisinopril, losartan	Chronic cough	Urinary leakage

Calcium-channel blockers	Nifedipine, nicardipine, isradipine, felodipine	Relaxes bladder, fluid retention	Urinary retention, nocturnal diuresis
Cyclooxygenase-2 selective NSAIDs	Celecoxib	Fluid retention	Nocturnal diuresis
Diuretics	Caffeine, HCTZ, furosemide, bumetanide, acetazolamide, spironolactone	Increases urinary frequency, urgency	Polyuria
Narcotic analgesics	Opiates	Relaxes bladder, fecal impaction, sedation	Urinary retention, and/or functional incontinence
Thiazolidinediones	Rosiglitazone, pioglitazone, troglitazone	Fluid retention	Nocturnal diuresis

HCTZ = hydrochlorothiazide; IUS = internal urethral sphincter; NSAID = nonsteroidal anti-inflammatory drug.

Physical Examination

GENERAL INSPECTION AND NEUROLOGIC EVALUATION

Initially, the perineum is inspected for evidence of atrophy, which may be noted throughout the lower genital tract. In addition, suburethral bulging may indicate a urethral diverticulum and should be excluded during inspection (see Chap. 26, Patient Signs and Symptoms).

A thorough physical examination for a woman with incontinence should also include a detailed neurologic evaluation of the perineum. Because neurologic responses may be altered in an anxious patient who is in a vulnerable setting, signs elicited during examination may not signify true pathology and should be interpreted with caution. Neurologic evaluation begins with attempting to elicit a *bulbocavernosus reflex.* During this test, one labium majora is stroked with a cotton swab. Normally, both labia equally contract bilaterally. The afferent limb of this reflex is the clitoral branch of the pudendal nerve, whereas its efferent limb is conducted through the inferior hemorrhoidal branch of the pudendal nerve. This reflex is integrated at the S2 to S4 spinal cord level (Wester, 2003). Thus, absence of this reflex may reflect central or peripheral neurologic deficits. Secondly, a normal circumferential anal sphincter contraction, colloquially called an "anal wink", should follow cotton swab brushing of the perianal skin. External urethral sphincter activity requires at least a degree of intact S2 to S4 innervation, and this *anocutaneous reflex* is mediated by the same spinal neurologic level. Thus, an absent wink may indicate neurologic deficits in this neurologic distribution.

PELVIC SUPPORT ASSESSMENT

Pelvic Organ Prolapse Evaluation

Poor urethral support commonly accompanies pelvic organ prolapse (POP). For example, women with significant prolapse are often unable to completely empty their bladder due to urethral kinking and obstruction. These women frequently must digitally elevate or reduce their prolapse to allow emptying. Thus, an external evaluation for POP, as described in Chapter 24, Physical Examination, is indicated for all women with urinary incontinence. Following this evaluation for vaginal compartment defects, pelvic muscle strength evaluation should also be performed. Women with mild to moderate urinary incontinence often respond well to pelvic floor therapy and under these circumstances, a trial of this therapy is warranted and often curative.

Q-Tip Test

If a urethra is poorly supported, it may display hypermobility during increases in intra-abdominal pressures. To assess mobility, a clinician places the soft end of a cotton swab into the urethra to the urethrovesical junction. Failure to insert the swab to this depth typically leads to errors in assessment of urethrovesical junction support. Termed the *Q-tip test,* this evaluation may be uncomfortable and application of intraurethral analgesia may prove helpful. Commonly, 1 percent lidocaine jelly is placed on the cotton swab prior to insertion. Following placement, Valsalva maneuver is prompted, and the swab angle excursion at rest and with

Valsalva maneuver is measured with a goniometer or standard protractor (Fig. 23-8). An angle excursion at rest or with Valsalva maneuver greater than 30 degrees above the horizontal indicates urethral hypermobility, and may help direct planning of surgical treatment for stress incontinence.

FIGURE 23-8

Drawing depicting Q-tip test in a patient with urethral hypermobility. **A.** Angle of the Q-tip at rest. **B.** Angle of the Q-tip with Valsalva maneuver or other increases in intra-abdominal pressure. The urethrovesical junction descends, causing upward deflection of the Q-tip. *(From Tarnay, 2007, with permission.)*

BIMANUAL AND RECTOVAGINAL EXAMINATION

In general, these portions of the pelvic examination provide fewer diagnostic clues to underlying causes of incontinence. However, bimanual examination may reveal an enlarged pelvic mass or a uterus enlarged by leiomyomas or adenomyosis. These may prompt incontinence through increased external pressure transmitted to the bladder. In addition, stool impaction is common in nursing home patients and may lead to bladder urgency and subsequent urinary incontinence.

Diagnostic Testing

URINALYSIS AND CULTURE

In all women with urinary incontinence, infection or urinary tract pathology must be excluded. Urinalysis and urine culture is sent at an initial visit. Infection is treated as described in Table 3-24, and persistent symptoms should prompt additional evaluation.

POSTVOID RESIDUAL

This volume is routinely measured during incontinence evaluation. After a woman voids, the postvoid residual (PVR) may be measured with a hand-held sonographic scanner or by transurethral catheterization. If using a hand-held scanner, care must be taken in women with an enlarged leiomyomatous uterus, as this may falsely record a large PVR. In these instances, or if a scanner is not available, transurethral catheterization may be used to confirm residual bladder volume.

A large postvoid residual may often reflect one of several problems, including recurrent infection, urethral obstruction from a pelvic mass, or neurologic deficits. In contrast, a normally small PVR is often found in those with stress urinary incontinence.

Postoperative Postvoid Residual

After anti-incontinence surgery, PVR measurement is a helpful indicator of a patient's ability to completely empty her bladder. This evaluation may be completed with a passive or an active voiding trial.

With a *passive voiding trial* , a urinary catheter is removed, and the PVR is measured by scanner or by transurethral catheterization after each voluntary void on two occasions. A voided volume of at least 300 mL and PVR less than 100 mL is desirable. However, adequate bladder emptying is assumed if the PVR is less than one third of the voided volume. If a patient does not meet these criteria, or if she is unable to void within 4 to 6 hours of discontinuing the urinary catheter, then a catheter is replaced and the test is repeated a day or more later.

During an *active voiding trial* , the bladder is actively filled with a set volume, and following patient voiding, residual bladder urine volumes are calculated. Initially, the bladder is completely emptied by catheterization. It may be helpful during catheterization for a woman to stand upright to clear the most dependent portions of her bladder. Sterile water is infused under gravity into the bladder through the same catheter until approximately 300 mL is used or until a subjective maximum capacity is reached. The patient is then asked to void spontaneously into a urine collection device. The difference between volume infused and volume retrieved is recorded as the postvoid residual (PVR). A residual of less than 100 mL or one third of the instilled volume, if less than 300 mL is infused, indicates adequate bladder emptying.

CYSTOMETRICS

Surgical correction of incontinence is invasive and not without risk. Moreover, the "bladder is an unreliable witness" and historical information may not always accurately indicate the true underlying type of incontinence (Blaivas, 1996). Thus, if initial conservative management is unsuccessful or surgical treatment is anticipated, then objective assessment should be pursued. In addition, if symptoms and physical findings are incongruous, then an objective urodynamic study (UDS), using cystometric evaluation, may also be indicated. For example, in women with mixed urinary incontinence, who have both symptoms of stress and urge urinary incontinence, UDS may reveal that only the urge component is responsible for their incontinence. Most of these women are treated with behavioral, physical, and/or pharmacologic therapy initially. Thus, if urge incontinence is identified by UDS, unnecessary surgery can be avoided. Additionally, surgical therapy may be modified if UDS reveals parameters consistent with intrinsic sphincteric defect.

Despite these indications, UDS remains controversial. Leakage noted during testing is not always clinically relevant. In contrast, testing may be uninformative if the original offending maneuver or situation that led to incontinence cannot be reproduced during evaluation. Moreover, objective confirmation of the diagnosis is not always necessary, since empiric therapy in women with urge-predominant symptoms is reasonable.

Simple Cystometrics

Objective measurements of bladder function are combined in a battery of tests termed *cystometrics.* Cystometrics may be *simple* or *multichannel* and differ in their sensitivity.

Simple cystometrics allows determination of stress incontinence and detrusor overactivity, as well as measurement of first sensation, desire to void, and bladder capacity. This procedure is easily performed with sterile water, a 60-mL catheter-tipped syringe, and urinary catheter, either Foley or Robnell. The urethra is sterilely prepared, the catheter is inserted, and the bladder is drained. A 60-mL syringe with its plunger removed is attached to the catheter and is filled with sterile water. Water is added in increments until a woman feels: (1) a sensation of bladder filling, (2) an urge to void, and (3) her bladder maximum capacity. Water volumes are noted at each three of these points. Changes in the fluid meniscus within the syringe are monitored. Any meniscus elevation indicates bladder contraction and establishes a diagnosis of detrusor overactivity. Once bladder capacity is reached, the catheter is removed, and the woman is asked to perform a Valsalva maneuver or cough while standing. Leakage indicates SUI.

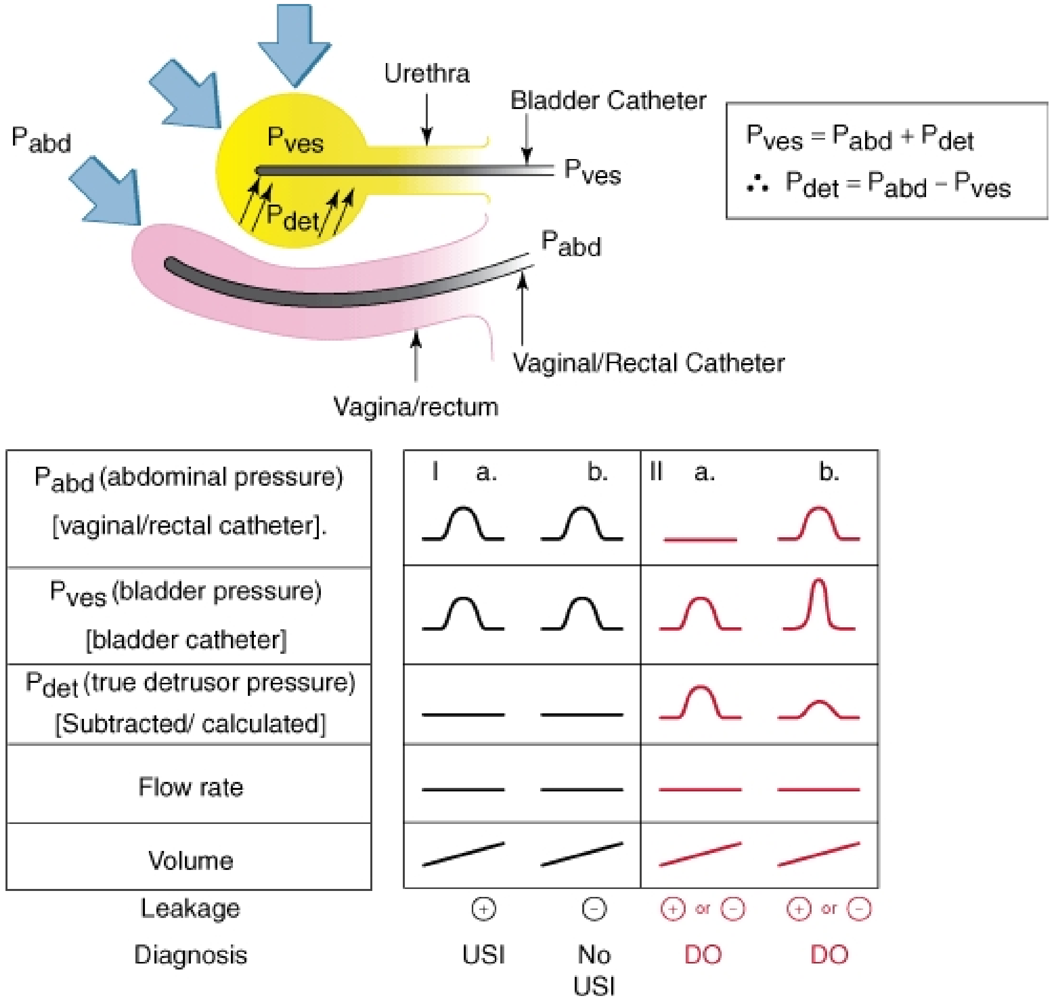
Advantageously, simple cystometrics are easy to perform, require inexpensive equipment, and can typically be completed by most gynecologists. One limitation of simple cystometric testing, however, is its inability to reflect changes found with intrinsic sphincteric deficiency (ISD).

Multichannel Cystometrics

As noted, simple cystometric testing does not identify ISD. This determination is important, since this diagnosis may potentially preclude certain surgical options. Additionally, multichannel cystometrics provides more information on other physiologic parameters of the bladder, not afforded by simple cystometrics.

Multichannel cystometrics is more commonly performed by urogynecologists or urologists due to limited equipment availability and increased costs. Testing can be performed with a woman standing or seated upright in a specialized urodynamics evaluation chair. During testing, two catheters are used. One is placed into the bladder and the other into either the vagina or rectum. The vagina is preferred unless advanced prolapse is evident because stool in the rectal vault may obstruct catheter sensors and lead to inaccurate readings. Additionally, vaginal placement for most women is more comfortable. From each of these two catheters, distinct pressure readings are obtained or calculated and include: (1) intra-abdominal pressure, (2) vesicular pressure, (3) calculated detrusor pressure, (4) bladder volume, and (5) saline infusion flow rate. From these catheter readings, information regarding bladder, intra-abdominal, and detrusor pressures can be obtained. As shown Figure 23-9, differentiation between the different forms of incontinence can be determined.

FIGURE 23-9



Interpretation of multichannel urodynamic evaluation: cystometrogram. A catheter is placed in the bladder to determine the pressure generated within it (P_{ves}). The pressure in the bladder is produced from a combination of the pressure from the abdominal cavity and the pressure generated by the detrusor muscle of the bladder.Bladder pressure (P_{ves}) = Pressure in abdominal cavity (P_{abd}) + Detrusor pressure (P_{det}). A second catheter is placed in the vagina (or rectum if advanced stage prolapse is present) to determine the pressure in the abdominal cavity (P_{abd}). As room temperature water is instilled into the bladder, the patient is asked to cough every 50 mL and the external urethral meatus is observed for leakage of urine around the catheter. The volume at first desire to void and the bladder capacity is recorded. Additionally, the detrusor pressure (P_{det}) channel is observed for positive deflections to determine if there is detrusor activity during testing. The detrusor pressure (P_{det}) cannot be measured directly by any of the catheters. However, from the first equation, we can calculate the detrusor pressure (P_{det}) by subtracting the bladder pressure from the abdominal pressure (P_{abd}):

Detrusor pressure (P_{det}) = Bladder pressure (P_{ves}) â€“ Pressure in abdominal cavity (P_{abd})

I. Urodynamic Stress Incontinence (USI)

Urodynamic stress incontinence is diagnosed when urethral leakage is seen with increased abdominal pressure, in the ABSENCE of detrusor pressure.

a. +USI (Column 1): Abdominal pressure is generated with Valsalva maneuver or cough. This pressure is transmitted to the bladder and a bladder pressure (P_{ves}) is noted. The calculated detrusor pressure is zero. Leakage is observed and diagnosis of USI is assigned.

b. No USI (Column 2): Abdominal pressure is generated with Valsalva maneuver or cough. This pressure is transmitted to the bladder and a bladder pressure (P_{ves}) is noted. The calculated detrusor pressure is zero. Leakage is NOT observed. The patient is NOT diagnosed as having

USI.

II. Detrusor Overactivity (DO)

Detrusor overactivity is diagnosed when the patient has involuntary detrusor contractions during testing with or without leakage.

a. +DO (Column 3): Although no abdominal pressure is observed, a vesicular pressure is noted. A calculated detrusor pressure is recorded and noted to be present. A diagnosis of DO is made regardless of whether leakage is seen or not.

b. +DO (Column 4): In this example, an abdominal pressure is observed as well as a vesicular pressure is noted. Using only the Pabd and the Pves channels, it is difficult to tell whether or not the detrusor muscle contributed to the pressure generated in the bladder. On subtraction, a calculated detrusor pressure is recorded. Thus, a diagnosis of DO is made, again regardless of whether leakage is seen or not.

In addition to these channels, occasionally a channel to detect electromyographic activity is used. Flow rate = rate of fluid infusion (usually 100 mL/min); P_{abd} = pressure in abdominal cavity; P_{det} = detrusor pressure (calculated); P_{ves} = bladder pressure; Vol = volume of fluid instilled in the bladder.

Uroflowmetry

Initially, women are asked to empty their bladder into a commode connected to a flowmeter (uroflow-metry). After a maximal flow rate is recorded, the patient is catheterized to measure a postvoid residual as well as to ensure an empty bladder prior to further testing. This test provides information on a woman's ability to empty her bladder. It can identify women with urinary retention and other types of voiding dysfunction.

Cystometrography

Following uroflowmetry, cystometrography is performed to determine whether a woman has urodynamic evidence of SUI or detrusor overactivity (DO). Moreover, this test provides information on bladder threshold volumes at which a woman senses bladder capacity. Delayed sensation or a sensation of bladder fullness only with large capacities may indicate neuropathy. Conversely, extreme bladder sensitivity may suggest sensory disorders such as interstitial cystitis.

For the cystometrogram, a 6F microtransducer catheter (Mikro-tip, Millar Instruments Inc., Houston, TX) is inserted transurethrally into the bladder, and a second catheter is inserted into the vagina. For women with advanced prolapse who may not be able to accommodate or retain the second catheter in their vagina, the second catheter is placed in the rectum. The bladder is filled with room temperature 0.9-percent normal saline at a rate of 100 mL/min using a cystometric pump. During filling, a woman is asked to cough at each 50-mL interval. Additionally during filling, the volumes at which a first desire to void and maximal bladder capacity are noted.

From pressure readings, DO and/or urodynamic SUI may be identified. Once 200 mL of saline has been instilled, an abdominal *leak point pressure* is measured. The patient is asked to perform a Valsalva maneuver, the pressure generated by the effort is measured, and evidence of urine leakage is sought. If leakage is seen when a pressure of less than 60 cm H_2O is generated, then criteria have been met for a diagnosis of intrinsic sphincteric deficiency.

At our institution, abdominal leak point pressures are measured at a bladder volume of 200 mL, using the true zero of intravesical pressure as the baseline. However, the volume at which this test is performed varies from institution to institution, with some choosing to use bladder capacity and others choosing to use 150 mL as the testing volume.

Pressure Flowmetry

This evaluation usually follows cystometrography and is similar to the uroflowmetry conducted at the beginning of urodynamic testing. A woman is asked to void into a beaker that rests on a calibrated weighted sensor. Maximum flow rate and postvoid residual are once again recorded. However, during voiding, a woman now has a microtip transducer catheter in her bladder, which provides additional information regarding detrusor pressure at maximum flow. This is particularly useful in women who may have incomplete bladder emptying. As noted earlier, in women with urinary retention, the offending source may be obstruction or poor detrusor contractility.

Urethral Pressure Profile

The final part of UDS testing is the urethral pressure profile. At our institution, we usually perform this test with a volume of 200

mL instilled in the bladder. However, again, this volume is often institution dependent. With a catheter transducer directed to a nine o'clock position within the bladder, the microtip dual-sensor catheter is pulled through the urethra with the aid of an automated puller arm (UPP Puller, Laborie Medical Technologies Corp., Williston, VT) at a speed of 1 mm/s. Maximum urethral closure pressure (MUCP) is determined by averaging three profiles. The *functional urethral length* and the *area of continence zone* are also obtained. This test provides valuable information on the intrinsic properties of the urethra and aids in the diagnosis of ISD. A diagnosis of ISD is made if the MUCP is 20 cm H_2O or less.

TREATMENT

Conservative/Nonsurgical

PELVIC FLOOR STRENGTHENING EXERCISES

Conservative management is a reasonable initial approach to most patients with urinary incontinence. The rationale behind conservative management is to strengthen the pelvic floor and provide a supportive backboard against which the urethra may close. Options include active pelvic floor exercises and passive electrical pelvic floor muscle stimulation. For both SUI and urge incontinence these fundamentals prove valuable. With SUI, pelvic floor strengthening is an attempt to compensate for anatomic defects. For urge incontinence, it improves pelvic floor muscle contraction to provide temporary continence during waves of bladder detrusor contraction.

Pelvic Floor Muscle Training (PFMT)

In women who have mild to moderate symptoms of urinary incontinence, pelvic floor muscle training (PFMT) may allow improvement if not cure. Also known as *Kegel exercises,* PFMT entails voluntary contraction of the levator ani muscles. As with any muscle building, exercise sets should be performed numerous times during the day, with some reporting up to 50 or 60 times each day.

Specific details in performance of these exercises are subject to clinician preference and clinical setting. In one variation of these exercises, isotonic contraction is used, and a woman is asked to squeeze and hold contracted levator ani muscles. Women, however, often have difficulty isolating these muscles. Frequently, women will erroneously contract their abdominal wall muscles rather than the levators during these exercises. To help localize the correct group, a woman may be instructed to identify the muscles that are tightened when snug pants are pulled up and over her hips. Moreover, in an office setting, a clinician can determine if the levator ani group is contracted by placing two fingers in the vagina while Kegel exercises are practiced.

Alternatively, a second variation of PFMT uses a method of rapid contraction and relaxation of the levators. This approach may prove advantageous if waves of urinary urgency strike. Of note, there is a misconception about the value of stopping urination midstream. Women should be counseled that this practice often worsens voiding dysfunction.

To augment efficacy of these exercises, weighted vaginal cones or obturators may be placed into the vagina during Kegel exercises. These provide resistance against which pelvic floor muscles can work.

Electrical Stimulation

As an alternative to active pelvic floor contraction, a vaginal probe may be used to deliver low-frequency electrical stimulation to the levator ani muscles. Although the mechanism is unclear, electrical stimulation may be used to improve either SUI or urge incontinence (Indrekvam, 2001; Wang 2004). With urge incontinence, traditionally a low frequency is applied, whereas higher frequencies are used for SUI. Electrical stimulation may be used alone or more commonly in combination with PFMT.

Biofeedback Therapy

Many behavioral techniques, often considered together as *biofeedback therapy,* measure physiologic signals such as muscle tension and then display them to a patient in real time. In general, visual, auditory, and/or verbal feedback cues are directed to the patient during these therapy sessions. These cues provide immediate performance evaluation to a patient. Specifically, during biofeedback for PFMT, a sterile vaginal probe that measures pressure changes within the vagina during levator ani muscle contraction is typically used. Readings reflect an estimate of muscle contraction strength. Treatment sessions are individualized, dictated by the

underlying dysfunction, and modified based on response to therapy. In many cases, reinforcing sessions at various subsequent intervals may also prove advantageous.

DIETARY

Different food groups that may have high acidity or caffeine content may lead to greater urinary frequency and urgency. Dallosso and colleagues (2003) found consumption of carbonated drinks to be associated with development of urge incontinence symptoms. Accordingly, elimination of these dietary irritants may prove beneficial for these women. In addition, certain supplements such as calcium glycerophosphate (Prelief, AkPharma, Pleasantville, NJ), when added to the diet have been shown to decrease urgency and frequency symptoms (Bologna, 2001). This is a phosphate-based product and is thought to buffer urine acidity.

SCHEDULED VOIDING

For women with urge urinary incontinence, voiding urges may occur as frequently as every 10 to 15 minutes. Initial goals are to extend actual voidings to half-hour intervals. Tools used to achieve this include Kegel exercises during waves of urgency or mental distraction techniques during these times.

Although used primarily for urge incontinence, scheduled voiding may also be helpful for those with SUI. For these patients, regularly scheduled urination leads to an empty bladder during a greater percentage of the day. Because some women will leak urine only if bladder volumes surpass specific threshold volumes, frequent emptying can significantly decrease incontinent episodes.

ESTROGEN REPLACEMENT

Estrogen has been shown to increase urethral blood flow and increase α-adrenergic receptor sensitivity, thereby increasing urethral coaptation and urethral closure pressure. In theory, estrogen may increase collagen deposition and increase vascularity of the periurethral capillary plexus. These are purported to improve urethral coaptation. Thus, for incontinent women who are atrophic, administration of exogenous estrogen is reasonable.

Estrogen is commonly administered topically. Many different regimens are appropriate and at our institution, we use conjugated equine estrogen cream (Premarin cream, Wyeth Pharmaceuticals, Philadelphia, PA) administered daily for 2 weeks, then twice weekly thereafter. Although no data are available to address the duration of treatment, women may be treated chronically with topical estrogen cream. Alternatively, oral estrogen may be prescribed if other menopausal symptoms for which estrogen would be beneficial co-exist (see Chap. 22, Summary of Current Use Indications).

However, despite these suggested benefits, a consensus regarding its beneficial effect on the lower urinary tract has not been as definitive. Specifically, studies have shown worsening or de novo development of urinary incontinence with systemic or topical estrogen administration (Hendrix, 2005; Jackson, 2006).

Treatment of Stress Urinary Incontinence

MEDICATIONS

Pharmaceutical treatment plays a minor role in the treatment of women with SUI. However, for women with mixed urinary incontinence, a trial of imipramine is reasonable to aid urethral contraction and closure. As discussed earlier, this tricyclic antidepressant has α-adrenergic effects and the urethra contains a high content of these receptors. Dosing can be found Table 23-5.

Table 23-5 Pharmacologic Treatment of Overactive Bladder				
Drug Name	**Brand Name**	**Drug Type**	**Dosage**	**Available Doses**
Oxybutynin (short-acting)	Ditropan	Antimuscarinic	2.5â€“5 mg PO tid	5-mg tablet, 5mg/mL syrup
Oxybutynin (long-acting)	Ditropan XL	See above	5â€“30 mg PO once daily	5-, 10-, 15-mg tablet
Oxybutynin (transdermal)	Oxytrol	See above	3.9 mg/d; patch changed twice weekly	36-mg patch
Tolterodine (short-acting)	Detrol	M_3 -selective antimuscarinic	1â€“2 mg PO bid	1-, 2-mg tablet
Tolterodine (long-acting)	Detrol LA	See above	2â€“4 mg PO once daily	2-, 4-mg capsule
Trospium chloride	Sanctura	Antimuscarinic quaternary amine	20 mg PO bid	20-mg tablet
Darifenacin	Enablex	M_3 -selective antimuscarinic	7.5â€“15 mg PO daily	7.5-, 15-mg tablet
Solifenacin	Vesicare	M_3 -selective antimuscarinic	5â€“10 mg PO once daily	5-, 10-mg tablets
Imipramine hydrochloride	Tofranil	Tricyclic antidepressant, anticholinergic, α -adrenergic, antihistamine	10â€“25 mg PO qdâ€“qid	10-, 25-, 50-mg tablets

bid = twice daily; PO = orally; qd = daily; qid = four times daily; tid = three times daily.

Recently, duloxetine (Cymbalta, Eli Lilly, Indianapolis, IN) a selective serotonin and norepinephrine reuptake inhibitor, has been evaluated for the treatment of SUI. In animal studies, serotonergic agonists suppress parasympathetic activity and enhance sympathetic and somatic activity. The sum effect promotes urine storage by relaxing the bladder and increasing outlet resistance. Although considered investigational, in randomized studies, this selective serotonin reuptake inhibitor (SSRI) has improved symptoms in women with SUI (Norton, 2002; Dmochowski, 2003a; Millard, 2004). Moreover, Ghoneim and co-workers (2005) in a randomized controlled trial evaluated the benefits of duloxetine, PFMT, and placebo combinations. Pad and quality of life data found the combination of duloxetine and PFMT to be more effective than either alone.

Previously, phenylpropanolamine (PPA) was used to treat SUI. However, in 2005, the Food and Drug Administration (FDA) reclassified PPA as category II and considered it as not generally safe or effective (U.S. Food and Drug Administration, 2005). Specifically, the FDA's decision was prompted by an increased rate of hemorrhagic strokes suffered by women taking this medication.

PESSARY AND URETHRAL INSERTS

Certain pessaries have been designed to treat incontinence as well as pelvic organ prolapse. Incontinence pessaries are designed to reduce downward excursion or funneling of the urethrovesical junction (see Chap. 24, Types of Pessaries). This provides bladder neck support and thereby helps to reduce incontinent episodes. Dependent on the amount of prolapse present, the efficacy of pessaries for treatment of urinary incontinence is variable. Not all women are appropriate candidates for pessaries, nor will all desire long-term management of incontinence or prolapse with these devices.

As an alternative to pessaries, a urethral insert may also be used for control of SUI. The only currently commercially available device is the *FemSoft* insert (Rochester Medical, Stewartville, MN) (Fig. 23-10). As the device is inserted, the sleeve slides into and

conforms to the urethra, creating a seal at the neck of the bladder to prevent accidental urine leakage. During routine bathroom visits, the insert is removed, discarded, and replaced with a fresh insert. Data are limited on the effectiveness of this insert. However, in an observational study of 150 women, Sirls and associates (2002) found significantly reduced rates of incontinence episodes.

B

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

A. Urethral insert used for continence. *(Courtesy of Rochester Medical.)* The device consists of a short silicone tube that is covered by a mineral oilâ€"containing sheath. The proximal end of the conformable sheath expands to a bulbous tip. At the device's distal end, a soft flange prevents migration of the entire tube into the bladder. **B.** For insertion, an applicator is used to aid placement. With insertion, mineral oil within the sheath is evenly distributed along its length, and the bulbous tip is collapsed. When properly placed, the tip enters the bladder and the mineral oil preferentially flows to the device's bulbous tip. The applicator is then removed. As a result, the bulbous tip occludes the urethra to improve continence. When voiding is desired, the flange is grasped and the entire single-use device is gently removed. *(Redrawn from Sirls, 2002, with permission.)*

SURGICAL TREATMENT OF INTRINSIC SPHINCTERIC DEFICIENCY

Periurethral Bulking Agents

Periurethral injection of bulking agents is indicated for women who have urodynamic stress incontinence associated with intrinsic sphincteric deficiency. Additionally, it is a useful alternative in women with SUI who have multiple medical problems and who are thus poor surgical candidates.

Agents are injected submucosally and elevate the urethral mucosa to improve coaptation. A number of available bulking materials are available for injection. These materials can be injected periurethrally or transurethrally, and the location of the injections can vary. Some recommend two locations on either side of the urethra, whereas others advocate injections in three or four quadrants. At our institution, we usually inject at the level of the urethrovesical junction at sites of apparent urethral mucosal defects. However, if a global defect is noted or if a discrete defect is absent, then a two- to four-quadrant approach is used. The specific steps of injection and types of products used are described in Section 42-6, Urethral Bulking Injections.

SURGICAL TREATMENT OF ANATOMIC STRESS INCONTINENCE

For those who are not adequately improved with or do not desire conservative management, surgery may be an appropriate next step for successful treatment of stress incontinence symptoms. As noted earlier, urethral support is integral to continence. Thus, surgical procedures that recreate this support often diminish or cure incontinence. Over 200 procedures have been developed for the surgical correction of SUI, although the complete physiology underlying their success is not entirely clear. In general, these surgical procedures are believed to prevent bladder neck and proximal urethra descent during increases in intra-abdominal pressure.

Transvaginal Needle Procedures and Paravaginal Defect Repair

Surgeries that correct urethral hypermobility are theorized to prevent bladder neck and proximal urethra descent during increases in intra-abdominal pressure. In the 1960s through 1980s, needle suspension procedures such as the Raz, Pereyra, and Stamey techniques were popular surgical treatments for SUI, but have now largely been replaced by other methods. In brief, these surgeries used specially designed ligature carriers to place sutures through the anterior vaginal wall and/or periurethral tissues and suspend them to various levels of the anterior abdominal wall. These relied on the strength and integrity of the periurethral tissue and abdominal wall strength for successful suspension.

Although initial cure rates were satisfactory, the durability of these procedures decreased with time. Success rates range from 50 to 60 percent, well below rates found with other current anti-incontinence procedures (Moser, 2006). Failure stemmed largely from "pull-through" of sutures at the level of the anterior vaginal wall.

Abdominal paravaginal defect repair (PVDR) is a surgical procedure that corrects lateral support defects of the anterior vaginal wall. The technique involves suture attachment of the lateral vaginal wall to the arcus tendineus fascia pelvis and is illustrated in Section 42-14, Abdominal Paravaginal Defect Repair. Currently, PVDR is primarily a prolapse operation. Although previously used to correct SUI, long-term data have revealed that this is no longer a superior method for primary treatment of SUI (Colombo, 1996; Mallipeddi, 2001).

Retropubic Urethropexy

This group of procedures includes the Burch and Marshall-Marchetti-Krantz (MMK) colposuspension procedures, which involve suspension and anchorage of the pubocervical fascia to the musculoskeletal framework of the pelvis (see Section 42-2, Burch Colposuspension). Long considered the gold standard for surgical treatment of SUI, the Burch technique uses the strength of the iliopectineal ligament (Cooper ligament) to lift the anterior vaginal wall and the periurethral and perivesicular fibromuscular tissue. In contrast, during MMK surgery, the periosteum of the pubic bone is used to suspend these tissues. Complications commonly associated with these procedures include creation of de novo detrusor overactivity, urinary retention, and in the case of the MMK, osteitis pubis. A recent study has suggested that performing a Burch retropubic urethropexy at the time of an abdominal sacrocolpopexy for vaginal vault prolapse may significantly reduce the development of symptomatic postoperative stress urinary incontinence (see Chap. 24, Concomitant Prolapse and Incontinence Surgery).

Pubovaginal Slings

With this surgery, a strip of either rectus fascia or fascia lata is placed under the bladder neck through the retropubic space. The ends are secured at the level of the rectus abdominis fascia (see Section 42-5, Pubovaginal Sling). Previously, cadaveric fascia was used as the suspension material. However, this tissue is eventually degraded and found not to be durable over time (FitzGerald, 1999; Howden, 2006). Currently, autologous fascia is preferred and is obtained from the rectus sheath, although fascia lata from the thigh is an alternative.

This surgery is a standard procedure for SUI. It has traditionally been used for SUI stemming from intrinsic sphincteric deficiency. In addition, this procedure may also be indicated for patients with prior failed anti-incontinence operations. Albo and associates (2007) compared pubovaginal sling using autologous fascia with Burch colposuspension for SUI. Higher success rates were found with the sling procedure after 2 years. However, greater rates of difficulty voiding and creation of de novo urge incontinence were noted with pubovaginal sling.

Midurethral Slings

A surge of these slings appeared on the market in the late 1990s and early part of this decade. There are many different variations of these procedures but all involve the midurethral placement of synthetic mesh. Simplistically they are classified based on the route of placement and can be subdivided into those using a retropubic placement or a transobturator approach. Of these, popular procedures include: (1) tension free vaginal tape (TVT), a retropubic method; and (2) the transobturator tape (TOT), a transobturator method.

Midurethral slings provide several advantages. First, these techniques are effective and short-term cure rates approximate 90 percent (Lim, 2006). Of the two, retropubic and transobturator approaches appear to offer comparable short-term continence results (deTayrac, 2004; Morey, 2006; Sung, 2007). Laurikainen and co-workers (2007) randomly assigned 267 women to undergo either type and found equal rates of subjective and objective cure.

Despite these favorable comparisons, long-term data regarding the efficacy of transobturator approaches are yet to be available. However, data obtained 17 months postoperatively showed an incontinence improvement rate of 89 percent for those with preoperative SUI (Juma, 2007). In contrast, long-term continence rates are known with the retropubic technique and these approximate 80 percent (Nilsson, 2004).

In addition to their effectiveness, the recovery from midurethral sling placement is rapid, and many gynecologists provide this surgery on an outpatient basis. However, as with other anti-incontinence surgeries, general risks for midurethral sling procedures include urinary retention, lower urinary tract and vascular injuries, and creation of de novo voiding dysfunction such as urgency and retention.

Retropubic Approach

There are several commercial kits available for this procedure. Of these, one of the more commonly used is the TVT (Gynecare, Piscataway, NJ). With a retropubic approach, each trocar is placed through a vaginal suburethral incision lateral to the urethra and brought out suprapubically through two skin incisions (see Section 42-3, Tension-Free Vaginal Tape). Alternatively, needles may be placed through the space of Retzius and into the vagina, in a "top-down" approach.

Transobturator Approach

As with retropubic placement, different kits for this approach are produced by several companies. Each contains variations of needle and mesh design, but in general, a permanent sling material, usually polypropylene, is placed (Fig. 23-11). Sling material is directed bilaterally through the obturator foramen and underneath the mid-urethra. The entry point overlies the proximal tendon of the adductor longus muscle. Initially, the TOT was developed to avoid common TVT complications, that is, lower urinary tract injury and vascular injury, mainly in the space of Retzius.

The two major types of TOT procedures are defined by whether needle placement begins inside the vagina and is directed outward, termed an *in-to-out* approach, or alternatively starts outside and is directed inward, called an *out-to-in* approach (see Section 42-4, Transobturator Tape Sling). Initially, this procedure was developed with an out-to-in approach. However, with this approach, bladder and urethral injury were potential complications. For example, in a retrospective study, Abdel-Fattah and colleagues (2006) compared these two approaches. Lower urinary injury to the bladder or ureter complicated 1 percent of nearly 400 procedures and all followed the out-to-in technique.

As a result, the in-to-out approach was created and marketed with the assertion of decreased lower urinary tract injury rates. However, with the in-to-out technique, trocar tips travel closer to the obturator neurovascular bundle than with the out-to-in method (Achtari, 2006; Zahn, 2007). Thus, although each method has its theoretical advantages, the possibility of injury is not entirely eliminated.

Although the transobturator approach provides an effective day-surgery technique with potentially lower rates of bladder injury, some retrospective studies have suggested that they may have limited effectiveness for patients who demonstrate urodynamic criteria for intrinsic sphincteric deficiency (Miller, 2006; O'Connor, 2006).

New Innovations

Modification of the TVT procedure is seen with the TVT Secur. With this new technique, a 3- to 4-inch strip of polypropylene synthetic mesh is placed directly below the mid-urethra through a small vaginal incision. With this technique, mesh is not threaded

through the retropubic space and avoids the potential for vascular injury in this space. However, no data on efficacy or safety are currently available. Moreover, lower urinary tract injury is not completely averted with this method. Other techniques that have been introduced include microwave ablation of the periurethral tissues. However, current data do not support the efficacy or safety of this method.

Treatment of Urge Incontinence

ANTICHOLINERGIC MEDICATIONS

Oxybutynin and Tolterodine

Drugs that competitively bind to cholinergic receptors may improve symptoms of urge incontinence and include tolterodine, oxybutynin, and imipramine. However, as discussed earlier, muscarinic receptors are not limited to the bladder. Thus, side effects with these drugs may be significant. Of these, dry mouth, constipation, and blurry vision are the most common (Table 23-6). Patients frequently report that dry mouth is a primary reason for drug discontinuation. Importantly, anticholinergics are contraindicated in those with narrow-angle glaucoma. Because of these effects, the therapeutic objective of bladder M_3 blockade with these antimuscarinic agents is often limited by the anticholinergic side effects. Accordingly, drug selection should be tailored, and efficacy is balanced against tolerability. For example, Diokno and colleagues (2003) found oxybutynin (Ditropan XL, Ortho-McNeil Pharmaceuticals, Raritan, NJ) to be more efficacious than tolterodine (Detrol LA, Pfizer, New York, NY). However, tolterodine was associated with lower rates of side effects.

Table 23-6 Potential Anticholinergic Side Effects

Side Effect	Potential Clinical Consequence
Increased pupil size	Photophobia
Decreased visual accommodation	Blurred vision
Decreased salivation	Gingival and buccal ulceration
Decreased bronchial secretions	Small airway mucus plugging
Decreased sweating	Hyperthermia
Increased heart rate	Angina, myocardial infarction
Decreased detrusor function	Bladder distention and urinary retention
Decreased gastrointestinal mobility	Constipation

With oxybutynin, most side effects stem from its secondary metabolite that follows its liver metabolism. Therefore, to minimize side effects from oral oxybutynin, a transdermal patch was designed to decrease the first-pass effect of this drug. This leads to decreased liver metabolism and fewer systemic cholinergic side effects. Dmochowski and co-workers (2003b) found fewer anticholinergic side effects with transdermal oxybutynin compared with long-acting oral tolterodine.

Transdermal oxybutynin (Oxytrol, Watson Pharma, Morristown, NJ) is supplied as a 7.6 × 5.7-cm patch that is applied twice weekly to the abdomen, hip, or buttock. Each patch contains 36 mg of oxybutynin and delivers approximately 3.9 mg each day. Application site pruritus is the most common side effect, and varying the site of application may minimize skin reactions.

Selective Muscarinic Receptor Antagonists

Newer anticholinergic medications have been introduced that aim to reduce side effects, which in turn improves quality of life as well as patient compliance. The agents are all M_3 -receptor-selective antagonists and include solifenacin (VESIcare, Yamanouchi Pharma, Paramus, NJ), trospium chloride (Santura, Esprit Pharma, East Brunswick, NJ), and darifenacin (Enablex, Novartis, East

Hanover, NJ). Advantages of increased urgency warning time and decreased muscarinic side effects have been shown in randomized controlled studies (Cardozo, 2004; Chapple, 2005; Haab, 2006; Zinner, 2004). However, although the side-effect profile of these drugs is attractive, they have not been proved superior to nonselective muscarinic receptor drugs in randomized controlled trials.

Imipramine

This agent is less effective than tolterodine and oxybutynin, but displays α-adrenergic as well as anticholinergic characteristics. Therefore, it is occasionally prescribed for those with mixed urinary incontinence. Importantly, doses of imipramine used to treat incontinence are significantly lower than those used to treat depression or chronic pain. In our experience, this minimizes the theoretical risk of drug-related side effects.

SACRAL NEUROMODULATION

This outpatient surgically-implanted device contains a pulse generator and electrical leads that are placed into the sacral foramina to modulate innervation to the bladder and pelvic floor. Sacral neuromodulation is reserved for women with refractory urgency, frequency, or urge incontinence. It may be also considered for those with pelvic pain, interstitial cystitis, and defecatory dysfunction, although it is not FDA-approved for these indications. Sacral neuromodulation is not considered primary therapy, and women have typically exhausted pharmacologic and conservative options when considering it.

Implantation is typically a two-stage process. Initially, leads are placed and attached to an externally worn generator (see Section 42-12, Sacral Neuromodulation). After placement, frequency and amplitude of electrical impulses can be adjusted and tailored to maximize effectiveness. If a 50-percent or greater improvement in symptoms is noted, then internal implantation of a permanent pulse generator is planned.

Although its use is limited, this modality has been shown to be effective for treatment of urinary symptoms. Studies have found improvement rates ranging from 60 to 75 percent, and cure rates approximating 45 percent (Janknegt, 2001; Schmidt, 1999; Siegel, 2000). This procedure is minimally invasive and is typically completed in a day-surgery setting. Accordingly, recovery is rapid. Surgical complications are rare but may include pain or infection at the generator insertion site.

EPIDEMIOLOGY

Pelvic organ prolapse is a health concern affecting millions of women worldwide. In the U.S., it is the third most common cited indication for hysterectomy. Moreover, a woman has an estimated lifetime risk of 11 percent to undergo surgery for prolapse or incontinence (Olsen, 1997). Despite the apparent prevalence of pelvic support problems, there are few studies of high epidemiologic quality to accurately estimate disease prevalence. This stems in part from a lack of consistent and valid clinical definitions (Weber, 2001a).

Although data are limited, studies show that the prevalence of pelvic organ prolapse increases steadily with age (Olsen, 1997; Swift, 2005). Given the condition's link to age and the changing demographics in the United States, the prevalence of pelvic floor disorders will undoubtedly grow.

RISK FACTORS

Table 24-1 summarizes predisposing factors for pelvic organ prolapse. Researchers agree that pelvic organ prolapse (POP) originates from multiple causes and develops gradually over a span of years. The relative importance, however, of each factor is not known.

Table 24-1 Risk Factors Associated with Pelvic Organ Prolapse
Pregnancy
Vaginal childbirth
Menopause
Aging
Hypoestrogenism
Chronically increased intra-abdominal pressure
Chronic obstructive pulmonary disease (COPD)
Constipation
Obesity
Pelvic floor trauma
Genetic factors
Race
Connective tissue disorders

Hysterectomy
Spina bifida

Obstetric-Related Risks

MULTIPARITY

Vaginal childbirth is the most frequently cited risk factor. There is no agreement whether it is pregnancy or parturition itself that predisposes to pelvic floor dysfunction. However, numerous studies have clearly shown that childbirth does increase a woman's propensity for developing POP. For example, in the Pelvic Organ Support Study (POSST), increasing parity was associated with advancing prolapse (Swift, 2005). Moreover, the risk of POP increased 1.2 times with each vaginal delivery. The Oxford family planning cohort study of 17,000 women showed that compared with nulliparous women, those with two deliveries had an eightfold increase in hospitalization for POP (Mant, 1997).

OTHER OBSTETRIC-RELATED RISKS

Although vaginal delivery is implicated in a woman's lifetime risk for POP, specific obstetric risk factors remain controversial. These include macrosomia, prolonged second-stage labor, episiotomy, anal sphincter laceration, epidural analgesia, forceps use, and oxytocin stimulation of labor. Each is a proposed risk factor, although not definitively proven. As we await further studies, we can anticipate that although each may have an important impact, it is the cumulative sum of all events occurring as the fetus traverses the birth canal that predisposes to POP.

Currently, two obstetric interventionsâ€”elective forceps delivery to shorten second-stage labor and elective episiotomyâ€”are not advocated because of a lack of evidence of benefit and their potential for maternal and fetal harm. First, forceps delivery is directly implicated in pelvic floor injury through its known association with anal sphincter laceration. Secondly, evidence of pelvic floor benefits from shortening the second stage of labor is lacking. For these reasons, elective forceps delivery is not recommended. Likewise, at least six randomized controlled trials comparing elective and selective episiotomy have shown no proven benefit, but an association with anal sphincter laceration, postpartum anal incontinence, and postpartum pain (Carroli, 2000).

ELECTIVE CESAREAN DELIVERY

Controversy has arisen over the topic of elective cesarean delivery to prevent pelvic floor dysfunction. Theoretically, if all women underwent cesarean delivery, there would be fewer women with pelvic floor dysfunction, including urinary incontinence and POP. Keeping in mind that most women do *not* develop pelvic floor dysfunction, elective cesarean delivery would subject many women to a potentially dangerous intervention who would otherwise not develop the problem. Specifically, given the 11 percent lifetime risk of undergoing surgery for incontinence or prolapse, for every one woman who would avoid pelvic floor surgery later in life by undergoing primary elective cesarean delivery, nine women would gain no benefit yet would nevertheless assume the potential risks of the cesarean. Most researchers agree that definitive recommendations will require further clinical studies to define the potential risks and benefits of elective cesarean delivery for primary prevention of pelvic floor dysfunction (Patel, 2006). At this point in time, recommendations regarding elective cesarean delivery to prevent pelvic floor dysfunction must be individualized.

Age

As described earlier, advancing age is also implicated in the development of POP. In the POSST study, there was a 100-percent increased risk of prolapse for each decade of life. In women aged 20 to 59 years, the incidence of POP roughly doubles with each decade. As with other risks for POP, aging is a complex process. The increased incidence may result from physiologic aging and degenerative processes as well as hypoestrogenism. Separating the effects of estrogen deprivation from the effects of the aging process is problematic.

Connective Tissue Disease

Women with connective tissue disorders may be more likely to develop POP. In a small case series study, one third of women with Marfan syndrome and three fourths of women with Ehlers-Danlos syndrome reported a history of POP (Carley, 2000).

Race

Racial differences in POP prevalence have been demonstrated in several studies (Schaffer, 2005). Black and Asian women show the lowest risk, whereas Hispanic women appear to have the highest risk (Kim, 2005). Although differences in collagen content have been demonstrated between races, racial differences in the bony pelvis may also play a role. For instance, black women more commonly have a narrow pubic arch and an android or anthropoid pelvis. These shapes are protective against POP compared with the gynecoid pelvis typical of most Caucasian women.

Increased Abdominal Pressure

Chronically increased intra-abdominal pressure is believed to play a role in POP pathogenesis. This condition is present with obesity, chronic constipation, chronic coughing, and repetitive heavy lifting. Numerous studies identify obesity as an independent risk factor for stress urinary incontinence (Brown, 1996; Burgio, 1991; Dwyer, 1988). However, the association with the development of POP is less clear (Hendrix, 2002; Nygaard, 2004). With regard to lifting, a Danish study demonstrated that nursing assistants who were involved with repetitive heavy lifting were at increased risk to undergo surgical intervention for prolapse, with an odds ratio of 1.6 (Jorgensen, 1994). In addition, cigarette smoking and chronic obstructive pulmonary disease (COPD) have also been implicated in the development of POP, although few data support this association (Gilpin, 1989; Olsen, 1997). Similarly, although chronic coughing results in repetitive increases in intra-abdominal pressure, no clear mechanism has been demonstrated. Some believe that the inhaled chemical compounds in tobacco may cause changes that lead to POP rather than the chronic cough itself (Wieslander, 2005).

DESCRIPTION AND CLASSIFICATION

Visual Descriptors

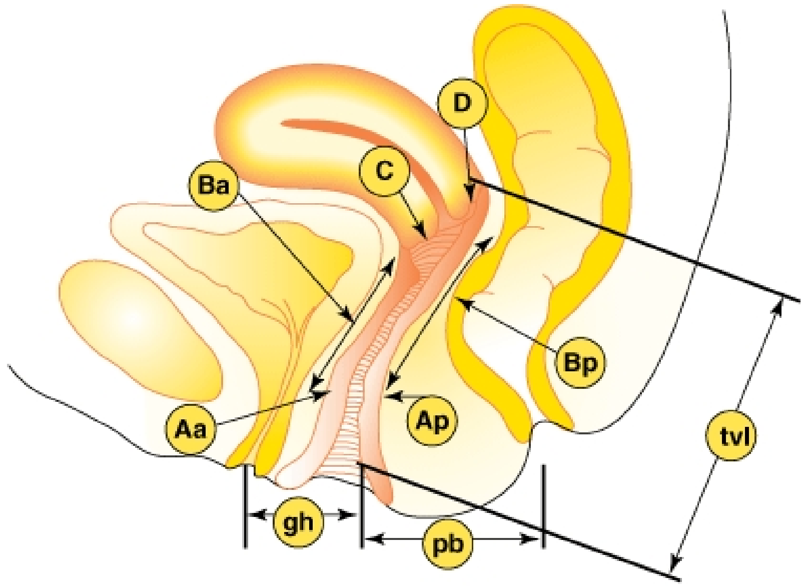
Prolapse is the downward displacement of one of the pelvic organs from its normal location that results in vaginal wall protrusion or bulge. The terms *cystocele, cystourethrocele, uterine prolapse, rectocele,* and *enterocele* have traditionally been used to describe the protrusion location. In specifying an organ, these terms imply that a vaginal bulge is with certainty caused by a herniation of the bladder, bladder/urethra, uterus, rectum, or small bowel, respectively. However, these terms are imprecise and misleading, as they focus on what is presumed to be prolapsed rather than what is actually seen. More importantly, such assumptions can lead to unforeseen problems. For example, a posterior vaginal prolapse that is presumed to be a rectocele may require an alternative reconstructive repair if an undetected enterocele is discovered at the time of surgery.

Although these terms are deeply entrenched in the literature, it is more clinically useful to describe prolapse in terms of what one actually sees: anterior vaginal wall prolapse, apical vaginal wall prolapse, cervical prolapse, posterior vaginal wall prolapse, perineal prolapse, and rectal prolapse. These descriptors do not presuppose what is behind the vaginal wall, but rather describe the tissues that are objectively noted to be prolapsed.

Pelvic Organ Prolapse Quantification (POP-Q)

In 1996, the International Continence Society defined a system of Pelvic Organ Prolapse Quantification (POP-Q) (Bump, 1996). Demonstrating high intra- and interexaminer reliability, the POP-Q system is a major advance in studying prolapse. It allows researchers to report findings in a standardized, easily reproducible fashion. This system contains a series of site-specific measurements of a woman's pelvic organ support. Prolapse in each segment is measured relative to the hymen, which is a fixed anatomic landmark that can be identified consistently. Six points are located with reference to the plane of the hymen: two on the anterior vaginal wall (points Aa and Ba), two in the apical vagina (points C and D), and two on the posterior vaginal wall (points Ap and Bp) (Fig. 24-1). All POP-Q points, except total vaginal length (tvl), are measured during patient Valsalva and should reflect maximum protrusion.

FIGURE 24-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Drawing displays the anatomic landmarks used during pelvic organ prolapse quantification (POP-Q).

ANTERIOR VAGINAL WALL POINTS

Point Aa

This term defines a point that lies in the midline of the anterior vaginal wall and is 3 cm proximal to the external urethral meatus. This corresponds to the proximal location of the urethrovesical crease. In relation to the hymen, this point's position ranges, by definition, from â€"3 (normal support) to +3 cm (maximum prolapse of point Aa).

Point Ba

This point represents the most distal position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to point Aa. It is â€"3 cm in the absence of prolapse. In a woman with total vaginal eversion post-hysterectomy, Ba would have a positive value equal to the position of the cuff from the hymen.

APICAL VAGINAL POINTS

Point C

The two apical points, C and D, which are located in the proximal vagina, represent the most proximal locations of a normally positioned lower reproductive tract. Point C defines a point that is at either the most distal edge of the cervix or the leading edge of the vaginal cuff after total hysterectomy.

Point D

This term defines a point that represents the location of the posterior fornix in a woman who still has a cervix. It is omitted in the absence of a cervix. This point represents the level of uterosacral ligament attachment to the proximal posterior cervix and thus differentiates uterosacral-cardinal ligament support failure from cervical elongation. The *total vaginal length* (TVL) is the greatest depth of the vagina in centimeters when point C or D is reduced to its fullest position.

POSTERIOR VAGINAL WALL POINTS

Point Ap

This term defines a point in the midline of the posterior vaginal wall that lies 3 cm proximal to the hymen. Relative to the hymen, this point's range of position is by definition â€"3 (normal support) to +3 cm (maximum prolapse of point Ap).

Point BP

This point represents the most distal position of any part of the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to point Bp. By definition, this point is at â€"3 cm in the absence of prolapse. In a woman with total vaginal eversion post-hysterectomy, Bp would have a positive value equal to the position of the cuff from the hymen.

Genital Hiatus and Perineal Body

In addition to the hymen, remaining measurements include those of the genital hiatus (gh) and the perineal body (pb) (see Fig. 24-1). The genital hiatus is measured from the middle of the external urethral meatus to the midline of the posterior hymenal ring. The perineal body is measured from the posterior margin of the genital hiatus to the mid-anal opening.

ASSESSMENT WITH POP-Q

With the hymenal plane defined as zero, the anatomic position of these points from the hymen is measured in centimeters. Points above or proximal to the hymen and are described with a negative number. Positions below or distal to the hymen are noted using a positive number. The point measurements can be organized using a three-by-three grid as shown in Fig. 24-2. Normal support is contrasted with complete post-hysterectomy vaginal eversion in Fig. 24-3, whereas Fig. 24-4 contrasts anterior with posterior vaginal wall prolapse.

FIGURE 24-2

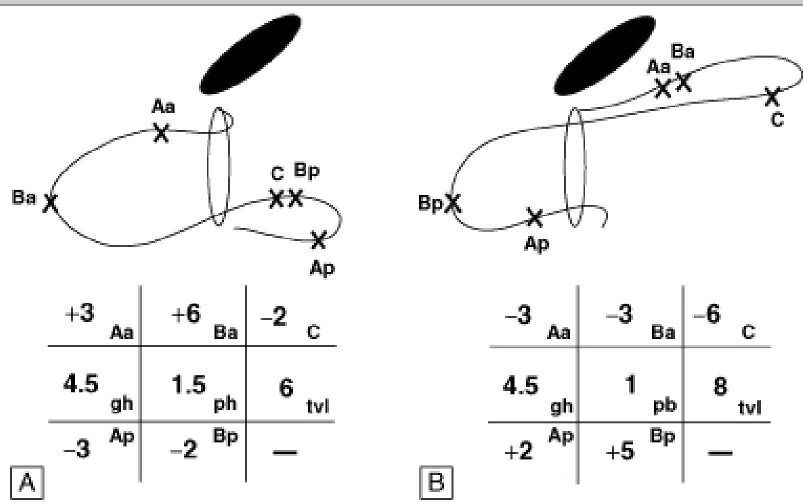
FIGURE 24-4



Grid and drawing of an anterior support defect **(A)** and posterior support defect **(B)** . *(Redrawn from Bump, 1996, with permission.)*

The degree of prolapse can also be quantified using a five-stage ordinal system as summarized in Table 24-2 (Bump, 1996). Stages are assigned according to the most severe portion of the prolapse.

Table 24-2 The Pelvic Organ Prolapse Quantification (POP-Q) Staging System of Pelvic Organ Support	
Stage 0:	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at â€“3 cm and either point C or D is between â€“TVL (total vaginal length) cm and â€“(TVLâ€“2) cm (i.e., the quantitation value for point C or D is ≤ â€“[TVL â€“ 2] cm). Fig. 24â€“3B represents stage 0.
Stage I:	The criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen (i.e., its quantitation value is < â€“ 1 cm).
Stage II:	The most distal portion of the prolapse is ≤1 cm proximal to or distal to the plane of the hymen (i.e., its quantitation value is ≥â€“1 cm but ≤+1 cm).
Stage III:	The most distal portion of the prolapse is >1 cm below the plane of the hymen but protrudes no further than 2 cm less than the total vaginal length in centimeters (i.e., its quantitation value is > + 1 cm but < + [TVLâ€“2] cm). Fig. 24â€“4A represents stage III Ba and Fig. 24â€“4B represents stage III Bp prolapse.
Stage IV:	Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (TVLâ€“2) cm (i.e., its quantitation value is ≥ +[TVLâ€“2] cm). In most instances, the leading edge of stage IV prolapse will be the cervix or vaginal cuff scar. Fig. 24â€“3A represents stage IV C prolapse.

Baden-Walker Halfway System

This descriptive tool is also used to classify prolapse on physical examination and is in widespread clinical use. Although not as informative as the POP-Q, it is adequate for clinical use if each compartment (anterior, apical, and posterior) is evaluated (Table 24-3) (Baden, 1972).

Table 24-3 Baden-Walker Halfway System for the Evaluation of Pelvic Organ Prolapse on Physical Examination[a]
Grade
Grade 0 Normal position for each respective site
Grade 1 Descent halfway to the hymen
Grade 2 Descent to the hymen
Grade 3 Descent halfway past the hymen
Grade 4 Maximum possible descent for each site

[a] Descent of the anterior vaginal wall, posterior vaginal wall, or apical prolapse can be graded with this system.

PATHOPHYSIOLOGY

Pelvic organ support is maintained by complex interactions between the levator ani muscle, vagina, and pelvic floor connective tissue. However, these mechanisms have not been fully delineated.

When the levator ani muscle has normal tone and the vagina has adequate depth, the upper vagina lies nearly horizontal in the standing female (see Fig. 38-9). This creates a "flap-valve" effect in which the upper vagina is compressed against the levator plate

during periods of increased intra-abdominal pressure. It is theorized that when the levator ani muscle loses tone, the vagina drops from a horizontal to a semi-vertical position. This widens or opens the genital hiatus and predisposes pelvic viscera to prolapse. Without adequate levator ani support, the visceral fascial attachments of the pelvic contents are placed on tension and are thought to stretch and eventually fail.

Mechanism of Levator Ani Damage

Skeletal muscle is a dynamic tissue that is constantly remodeling and regenerating. A heterogeneous population of fibers with different functions allows skeletal muscle to adapt to different situations, such as stretch and mechanical load. Damage to the levator ani muscles follows direct muscle tissue injury or may result from damage to its nerve supply. Labor and vaginal delivery has the potential to cause this type of damage. However, it is unclear what effect other pathologic conditions, such as chronically increased intra-abdominal pressure, may have on the levator ani muscle.

DIRECT INJURY

Direct injury to the levator ani muscles is believed to occur during second-stage labor. The muscle undergoes significant stretch as the fetal head distends the pelvic floor. Specifically, computer-simulated models that recreate labor stresses show that, of the levator ani muscles, the medial pubococcygeus muscles undergo the most stretch (Lien, 2004). Moreover, Tunn and associates (1999) used magnetic resonance (MR) imaging to describe the levator ani muscle after vaginal delivery in 14 women. They found the urogenital and levator hiatus areas to be increased immediately postpartum compared with second scans obtained 2 weeks later. This suggests that the levator ani muscles actually remodel and recover in some women after vaginal delivery.

This appears to be true functionally as well. Postpartum women have been found to have decreased pelvic floor muscle strength after delivery but have return of function by 10 weeks (Peschers, 1997). However, it is also likely that in some cases permanent stretch injury occurs. Evidence for this is suggested by the clinical observation that multiparous women have a widened genital hiatus compared with nulliparous women.

NEUROLOGIC INJURY

Nerve injury is a suspected risk factor for POP. In addition to anatomic studies, pudendal nerve terminal motor latencies (PNTML) and electromyography (EMG), described in Chapter 25, Electromyography, have been used to investigate neural damage after vaginal delivery. From these studies, there is evidence that pudendal neuropathy is associated with vaginal delivery (Snooks, 1990). It is proposed that stretch injury of the pudendal nerve occurs during second-stage labor because the nerve is fixed as it exits Alcock canal (see Fig. 38-30) (Benson, 1999). Alternatively, chronic straining with defecation has also been associated with pelvic muscle denervation (Jones, 1987; Lubowski, 1988; Snooks, 1985). Excess straining and perineal descent can stretch the pudendal nerves and result in neuropathy (Kiff, 1984). However, despite these associations between neuropathy and vaginal delivery or chronic constipation, data supporting an association or causation between pudendal neuropathy and POP are lacking (Barber, 2002; Snooks, 1985).

Mechanism of Vaginal Wall Injury

The vaginal wall is comprised of squamous epithelium, smooth muscle muscularis, and adventitia. All elements are embedded in an extracellular matrix that includes collagen, elastin fibers, and smooth muscle. Abnormalities of these components may contribute to vaginal dysfunction and development of POP.

SITE-SPECIFIC DEFECTS

This theory is based on the premise that tears in the "endopelvic fascia" surrounding the vaginal wall allow herniation of the pelvic organs. The association of POP with vaginal delivery is consistent with this theory. However, study of the microscopic anatomy of the vaginal wall indicates that endopelvic fascia does not exist as a specific anatomic tissue, but rather represents the fibromuscular layer of the vaginal wall, that is, vaginal muscularis and adventitia (Fig. 24-5) (Boreham, 2001).

FIGURE 24-5

Photomicrograph shows a complete cross section of the vaginal wall. The fibromuscular layer is comprised of muscularis and adventitia, which lies deep to the muscularis. *(Courtesy of Dr. Ann Word.)*

Although most researchers agree that vaginal delivery predisposes women to POP, there is less agreement regarding changes in the pelvic musculature and vaginal wall that result in prolapse. Nichols and Randall (1989) proposed an attenuation of the vaginal wall without loss of fascial attachments. They term prolapse of this type as *distention* cystocele or rectocele (Fig. 24-6). In contrast, anterior and posterior wall defects due to loss of the connective tissue attachment of the lateral vaginal wall to the pelvic side wall are described as *displacement* (paravaginal) cystocele or rectocele (Fig. 24-7). With distention type prolapse, the vaginal wall appears smooth and without rugae, due to attenuation. With displacement type prolapse, vaginal rugae are visible. Both defect types could result from the stretching or tearing of support tissues during second-stage labor.

FIGURE 24-6

Photograph shows a lateral cystocele, also termed paravaginal or displacement cystocele. Rugae are present, which indicates that loss of support is lateral rather than central.

SMOOTH MUSCLE DYSFUNCTION

Abnormalities in the anatomy, physiology, and cellular biology of vaginal wall smooth muscle may contribute to POP. For example, smooth muscle fibers arising from the vaginal wall attach to the levator ani complex (DeLancey, 1990). Dysfunction of this smooth muscle may affect the attachment of the lateral vagina to the pelvic side wall. Additionally, the fraction of smooth muscle in the muscularis of the anterior and posterior vaginal wall apex in women with prolapse is decreased compared with women without prolapse (Boreham, 2002a, 2002b). Decreased smooth muscle content of the round ligament in women with POP has also been described (Ozdegirmenci, 2005).

CONNECTIVE TISSUE ABNORMALITIES

The connective tissue of the pelvis is comprised of collagen, elastin, smooth muscle, and microfibers, which are anchored in an

extracellular matrix of polysaccharides. The connective tissue that invests the pelvic organs provides substantial anatomic support of the pelvis and its contents. There is evidence that suggests abnormalities of connective tissue and connective tissue repair may predispose women to prolapse (Norton, 1995; Smith 1989). Women with connective tissue disorders such as Ehlers-Danlos or Marfan syndrome are more likely to develop POP and urinary incontinence (Carley, 2000; Norton, 1995).

Decreased collagen content is found in women with stress urinary incontinence and POP. Compared with women displaying normal pelvic organ support, those with prolapse were found to have less total collagen in their "pubocervical fascia" as well as a weaker type of collagen (Jackson, 1996; Makinen, 1986). This may be secondary to increased collagen degradation. Specifically, analysis of collagen in prolapsing tissue has found structural, biochemical, and quantitative differences in collagen content (Boreham, 2001).

The fascia and connective tissues of the pelvic floor may also lose strength consequent to aging and loss of neuroendocrine signaling in pelvic tissues (Smith, 1989). Estrogen deficiency can affect the biomedical composition, quality, and quantity of collagen. Estrogen influences collagen content by increasing synthesis or decreasing degradation. Exogenous estrogen supplementation has been found to increase the skin collagen content in postmenopausal women who are estrogen deficient (Brincat, 1983). Estrogen supplementation prior to prolapse surgery, and/or postoperatively, is considered essential by many prolapse surgeons. Although this practice may seem logical and empirically sound, no evidence exists to suggest improved surgical outcomes with this use of adjuvant estrogen.

Levels of Vaginal Support

The vagina consists of a fibromuscular, flattened, cylindrical tube with three levels of support, as described by DeLancey (1992) (see Fig. 38-11). Level I support suspends the upper or proximal vagina. Level II support attaches the mid-vagina along its length to the arcus tendineus fascia pelvis. Level III support results from fusion of the distal vagina to adjacent structures. Defects in each level of support result in identifiable vaginal wall prolapse: anterior, apical, and posterior.

It is notable that the three levels of support are interconnected through a loose fibromuscular connective tissue network. As it envelops the pelvic organs, this fibromuscular connective tissue network connects these organs loosely to supportive musculature and bony pelvis. Composed of collagen, elastin, adipose tissue, nerves, blood vessels, lymphatic channels, and smooth muscle, this loose fibromuscular connective tissue network provides stabilization and support, yet allows mobility, expansion, and contraction of viscera. As such, normal pelvic support is provided by complex interaction between the pelvic floor muscles, connective tissue attachments, and the bony pelvis.

LEVEL I SUPPORT

This level consists of the cardinal and uterosacral ligaments attachment to the cervix and upper vagina. The cardinal ligaments fan out laterally and attach to the parietal fascia of the obturator internus and piriformis muscles, the anterior border of the greater sciatic foramen, and the ischial spines. The uterosacral ligaments are posterior fibers that attach to the presacral region at the level of S2 through S4. Together, this dense visceral connective tissue complex maintains vaginal length and horizontal axis. It allows the vagina to be supported by the levator plate and positions the cervix just superior to the level of the ischial spines. Defects in this support complex may lead to apical prolapse. This is frequently associated with small bowel herniation into the vaginal wall, that is, enterocele.

LEVEL II SUPPORT

This support consists of the paravaginal attachments that are contiguous with the cardinal/uterosacral complex at the ischial spine. These are the connective tissue attachments of the lateral vagina anteriorly to the arcus tendineus fascia pelvis and posteriorly to the arcus tendineus rectovaginalis. Detachment of this connective tissue from the arcus tendineus fascia pelvis leads to lateral or paravaginal anterior vaginal wall prolapse.

LEVEL III SUPPORT

The perineal body, superficial and deep perineal muscles, and fibromuscular connective tissue comprise level III. Collectively, these support the distal one-third of the vagina and introitus. The perineal body is essential for distal vaginal support as well as proper function of the anal canal. Damage to level III support contributes to anterior and posterior vaginal wall prolapse, gaping introitus,

and perineal descent.

EVALUATION OF THE PATIENT WITH PELVIC ORGAN PROLAPSE

Symptoms Associated with Pelvic Organ Prolapse

Pelvic organ prolapse involves multiple anatomic and functional systems, and is commonly associated with genitourinary, gastrointestinal, and musculoskeletal symptoms (Table 24-4). Prolapse rarely results in severe morbidity or mortality, however, it can greatly diminish quality of life. Therefore, initial evaluation must include a careful assessment of prolapse-related symptoms and their affect on activities of daily living.

Table 24-4 Symptoms Associated with Pelvic Organ Prolapse

Symptoms	Other Possible Causes
Bulge symptoms	
Sensation of vaginal bulging or protrusion	Rectal prolapse
Seeing or feeling a vaginal or perineal bulge	Vulvar or vaginal cyst/mass
Pelvic or vaginal pressure	Pelvic mass
Heaviness in pelvis or vagina	Hernia (inguinal or femoral)
Urinary symptoms	
Urinary incontinence	Urethral sphincter incompetence
Urinary frequency	Detrusor overactivity
Urinary urgency	Hypoactive detrusor function
Weak or prolonged urinary stream	Bladder outlet obstruction (i.e., postsurgical)
Hesitancy	Excessive fluid intake
Feeling of incomplete emptying	Interstitial cystitis
Manual reduction of prolapse to start or complete voiding	Urinary tract infection
Position change to start or complete voiding	
Bowel symptoms	
Incontinence of flatus or liquid/solid stool	Anal sphincter disruption or neuropathy
Feeling of incomplete emptying	Diarrheal disorder
Hard straining to defecate	Rectal prolapse
Urgency to defecate	Irritable bowel syndrome
Digital evacuation to complete defecation	Rectal inertia
Splinting vagina or perineum to start or complete defecation	Pelvic floor dyssynergia

Feeling of blockage or obstruction during defecation	Hemorrhoids
	Anorectal neoplasm
Sexual symptoms	
Dyspareunia	Vaginal atrophy
Decreased lubrication	Levator ani syndrome
Decreased sensation	Vulvodynia
Decreased arousal or orgasm	Other female sexual disorder
Pain	
Pain in vagina, bladder, or rectum	Interstitial cystitis
Pelvic pain	Levator ani syndrome
Low back pain	Vulvodynia
	Lumbar disc disease
	Musculoskeletal pain
	Other causes of chronic pelvic pain

From Barber, 2005a, with permission.

Symptoms should be carefully reviewed to determine if they are caused by the prolapse or by other etiologies. For example, bulge or pressure symptoms are often the direct result of prolapse. In contrast, chronic straining during defecation may be a cause rather than a result of prolapse. A thorough history and physical examination will often help delineate the relationship between POP and symptoms.

During symptom inventory, several tools may be useful in assessing severity. Two commonly used questionnaires are the Pelvic Floor Distress Inventory (PFDI) and the Pelvic Floor Impact Questionnaire (PFIQ) (Barber, 2005b). The PFDI assesses urinary, colorectal, and prolapse symptoms, whereas the PFIQ assesses the impact of prolapse on quality of life (Tables 24-5 and 24-6).

Table 24-5 Short Form: Pelvic Floor Impact Questionnaire 7-Item (PFIQ-7)

Please select the best answer to each question below.

Name ______________________________

Has your prolapse affected your:

1. Ability to do household chores (cooking, house cleaning, laundry)?
   _ Not at all _ Mildly _ Moderately _ Severely
2. Physical recreation such as walking, swimming, or other exercises?
   _ Not at all _ Mildly _ Moderately _ Severely
3. Entertainment activities (movies, church)?
   _ Not at all _ Mildly _ Moderately _ Severely
4. Ability to travel by car or bus more than 30 minutes from home?
   _ Not at all _ Mildly _ Moderately _ Severely
5. Participation in social activities outside your home?
   _ Not at all _ Mildly _ Moderately _ Severely
6. Emotional health (nervousness, depression)?
   _ Not at all _ Mildly _ Moderately _ Severely
7. Feeling frustrated?
   _ Not at all _ Mildly _ Moderately _ Severely

From Flynn, 2006, with permission.

Table 24-6 Short Form: Pelvic Floor Distress Inventory 22-Item (PFDI-22)[a]
POPDIâ€"6
Do you usually_____________, and if so how much are you bothered by: 1. experience pressure in the lower abdomen 2. experience heaviness or dullness in the abdomen or genital area 3. have a bulge or something falling out that you can see or feel in the vaginal area 4. have to push on the vagina or around the rectum to have or complete a bowel movement 5. experience a feeling of incomplete bladder emptying 6. have to push up on a bulge in the vaginal area with your fingers to start or complete urination
CRADIâ€"8
_____________, and if so how much are you bothered by it? 1. Do you usually feel you need to strain too hard to have a bowel movement 2. Do you usually feel you have not completely emptied your bowels at the end of bowel movement 3. Do you usually lose stool beyond your control if your stool is well formed 4. Do you usually lose stool beyond your control if your stool is loose or liquid 5. Do you usually lose gas from the rectum beyond your control 6. Do you usually have pain when you pass your stool 7. Do you usually experience a strong sense of urgency and have to rush to the bathroom to have abowel movement 8. Does part of your bowel ever pass through the rectum and bulge outside during or after a bowel movement
UDIâ€"8
Do you usually have _____________, and if so, how much are you bothered by: 1. frequent urination 2. leakage related to feeling of urgency 3. leaking related to activity, coughing, or sneezing 4. leakage when you go from sitting to standing 5. small amounts of urine leakage (i.e., drops) 5. difficulty emptying the bladder 7. pain or discomfort in the lower abdomen or genital area 8. pain in the middle of your abdomen as your bladder fills

[a] For each question, patients fill in the blank with each phrase underneath the question. The same multiple choice responses (not at all, mildly, moderately, and severely) used for the PFIQ-7 are used for the PFDI-22.

From Flynn, 2006, with permission.

Treatment is symptom-directed and in the absence of complaints, prolapse generally does not require therapy. However, for those with symptoms, treatment may include both nonsurgical and surgical therapy.

BULGE SYMPTOMS

Two of the most common symptoms associated with prolapse are the sensation or visualization of a vaginal or perineal protrusion, and the sensation of pelvic pressure. Women with these symptoms often complain of feeling a ball in the vagina, sitting on a weight, or noting a bulge rubbing on their clothes. These symptoms appear to worsen with prolapse progression (Ellerkmann, 2001). If bulge symptoms are the primary complaint, successful replacement of the prolapse with nonsurgical or surgical therapy will usually provide adequate treatment.

URINARY SYMPTOMS

Patients with POP often have concurrent urinary symptoms including stress urinary incontinence (SUI), urge urinary incontinence, frequency, urgency, urinary retention, recurrent urinary tract infection, or voiding dysfunction. Although these symptoms may be caused or exacerbated by prolapse, it should not be assumed that surgical or nonsurgical correction of prolapse will be curative. For example, irritative bladder symptoms (frequency, urgency, and urge urinary incontinence) do not reliably improve with replacement of prolapse and sometimes worsen after surgical management. Moreover, they may be unrelated to the prolapse and require alternative therapy. In contrast, urinary retention has been found to improve with prolapse treatment if the symptom is due to an obstructed urethra (FitzGerald, 2000).

For these reasons, urodynamic testing is a valuable adjunct in women with urinary symptoms who are undergoing treatment of prolapse (see Chap. 23, Cystometrics). This testing attempts to determine the relationship between urinary symptoms and POP and will help guide therapy. Additionally, consideration may also be given to temporarily placing a pessary prior to surgery to determine if urinary symptoms improve, and thereby predict whether surgical reduction of prolapse will be beneficial.

GASTROINTESTINAL SYMPTOMS

Constipation is often present in women with pelvic organ prolapse. However, replacement of prolapse either by surgical repair or with a pessary does not usually cure constipation and may actually worsen it. In one study of defect-directed posterior repair, constipation resolved postoperatively in only 43 percent of patients (Kenton, 1999). Therefore, if a patient's primary symptom is constipation, treatment of prolapse may not be indicated. Constipation should be viewed as a problem distinct from prolapse and evaluated separately (see Chap. 25, Rectoanal inhibitory reflex).

The need for digital decompression of the posterior vaginal wall, the perineal body, or the distal rectum to evacuate the rectum is the most common defecatory symptom associated with posterior vaginal wall prolapse (Barber, 2003; Burrows, 2004; Ellerkmann, 2001). Surgical approaches to this problem result in variable success, with symptom resolution rates as low as 36 percent (Kenton, 1999).

Anal incontinence of flatus or liquid or solid stool may also be seen in conjunction with POP. On occasion, prolapse may lead to stool trapping in the distal rectum with subsequent leakage of liquid stool around retained feces. If symptoms are present, a full anorectal evaluation should be performed (see Chap. 25, Physical Examination). Most types of anal incontinence would not be expected to improve with surgical repair of prolapse. However, if evaluation reveals an anal sphincter defect as the cause of anal incontinence, anal sphincteroplasty may be performed concurrently with prolapse repair.

SEXUAL DYSFUNCTION

Sexual dysfunction is often seen in women with POP. The etiology is frequently multifactorial and includes psychosocial factors, urogenital atrophy, aging, and male sexual dysfunction (see Chap. 13, Female Sexuality). Studies related to sexual function in women with prolapse are limited. In one study, a validated sexual function questionnaire was used to compare frequency of intercourse, libido, dyspareunia, orgasmic function, and vaginal dryness in women with and without prolapse (Weber, 1995). No differences were seen between the two groups. However, if a patient with POP describes an obstructing bulge as causing sexual dysfunction, therapy to reduce the bulge may be beneficial. Unfortunately, some prolapse procedures such as posterior repair with levator plication are believed to contribute to postoperative dyspareunia. Therefore, care should be taken in planning appropriate surgical procedures for women with concomitant sexual dysfunction.

PELVIC AND BACK PAIN

Many patients with pelvic organ prolapse complain of pelvic and low back pain, but there is little evidence to suggest a direct association. A cross-sectional study of 152 consecutive patients with POP did not find an association between pelvic or low back

pain and prolapse after controlling for age and prior surgery (Heit, 2002). Swift and colleagues (2003) found that back and pelvic pain were common among 477 women presenting for routine annual gynecologic examination and had no relationship to POP.

Some suggest that low back pain in a patient with prolapse may be caused by altered body mechanics. However, if pain is a primary symptom, other sources should be sought (see Chap. 11, Chronic Pain). In the absence of an identifiable etiology, temporary pessary placement is often beneficial to determine whether prolapse reduction will improve pain symptoms. Referral to a physical therapist may also shed light on a connection among prolapse, altered body mechanics, and pain.

ASYMPTOMATIC WOMEN

Many women with mild to advanced prolapse lack bothersome symptoms. Because the natural history of prolapse is unknown, it is difficult to predict if prolapse will worsen or if symptoms will develop. In this situation, benefits of treatment should be balanced against risk. Therefore, in the absence of other factors, invasive therapy is typically not selected for asymptomatic women. Pelvic floor muscle rehabilitation may be offered to a patient seeking to prevent prolapse progression. However, no data support the effectiveness of this practice (Adams, 2004; Hagen, 2004).

COMPARING SYMPTOMS TO DEGREE AND LOCATION OF PROLAPSE

Although POP has been associated with several different types of symptoms, the presence and severity of symptoms does not correlate well with advancing stages of prolapse. In addition, many common symptoms do not differentiate between compartments. Several studies have shown a poor predictive value among symptoms, the degree of their severity, and the degree of prolapse in a particular vaginal compartment (Ellerkmann, 2001; Jelovsek, 2005; Kahn, 2005; Weber, 1998). Thus, when planning surgical or nonsurgical therapy, realistic expectations should be set with regard to relief of symptoms. A patient should be informed that some symptoms cannot predictably be improved.

Physical Examination

Physical examination begins with a full body systems evaluation to identify pathology outside the pelvis. Systemic conditions such as cardiovascular, pulmonary, renal, or endocrinologic disease may affect treatment choices and should be identified early.

PERINEAL EXAMINATION

Initial pelvic examination is performed with a woman in lithotomy position. The vulva and perineum are examined for signs of vulvar or vaginal atrophy, lesions, or other abnormalities. A neurologic examination of sacral reflexes is performed using a cotton swab (see Chap. 23, General Inspection and Neurologic Evaluation). First, the *bulbocavernosus reflex* is elicited by tapping or stroking lateral to the clitoris and observing contraction of the bulbocavernosus bilaterally. Secondly, evaluation of anal sphincter innervation is completed by stroking lateral to the anus and observing a reflexive contraction of the anus, known as the *anal wink reflex* . The presence of these reflexes suggests normal sacral pathways. However, they may be absent in women who are neurologically intact, due to false-negative testing.

Pelvic organ prolapse examination begins by asking a woman to attempt Valsalva maneuver prior to placing a speculum in the vagina (Fig. 24-8). Patients who are unable to adequately complete a Valsalva maneuver are asked to cough. This "hands-off" approach more accurately displays true anatomy. With speculum examination, structures are artificially lifted, supported, or displaced. Importantly, this assessment helps answer three questions: (1) Does the protrusion come beyond the hymen?; (2) What is the presenting part of the prolapse (anterior, posterior, or apical)?; (3) Does the genital hiatus significantly widen with increased intra-abdominal pressure?

Photographs of vaginal wall prolapse. **A.** Stage 2. This stage is defined by the most distal edge of the prolapse lying within 1 cm of the hymenal ring. **B.** Stage 3. This stage is defined by the most distal portion of the prolapse being >1 cm below the plane of the hymen, but protruding no farther than 2 cm less than the total vaginal length in centimeters. **C.** Stage 4. This stage is defined as complete or near complete eversion of the vaginal wall.

During examination, a clinician should verify that the full extent of the prolapse is being seen. Specifically, a woman should be asked to describe the extent of prolapse during real-life activities. This degree may be conveyed in terms of inches. Alternatively, a mirror may be placed at the perineum and visual confirmation can be obtained from the patient.

Prolapse is a dynamic condition that responds to the effects of gravity and intra-abdominal pressure. It frequently worsens over the course of a day or during physical activity. If the full extent of prolapse cannot be demonstrated, a woman should be examined in a standing position and during Valsalva maneuver.

VAGINAL EXAMINATION

If the POP-Q examination is performed, the genital hiatus (gh) and perineal body (pb) are measured during Valsalva maneuver (Fig. 24-9). The total vaginal length (TVL) is then measured by placing the marked ring forceps at the vaginal apex and noting the distance to the hymen. A bivalve speculum is then inserted to the vaginal apex. It displaces the anterior and posterior vaginal walls, and points C and D are then measured. The speculum is slowly withdrawn to assess descent of the apex. A split speculum is then used to displace the posterior vaginal wall and allow for visualization of the anterior wall and measurement of points Aa and Ba (Fig. 24-10). Attempts are made to characterize the nature of the anterior vaginal wall defect. Sagging lateral vaginal sulci with vaginal rugae still present suggest a *paravaginal defect* , that is, a lateral loss of support (Fig. 24-11B). A central bulge and loss of vaginal rugae is called a *midline* or *central defect* (see Fig. 24-6). If loss of support appears to arise from detachment of the anterior vaginal wall's apical segment from the apex, it is termed a *transverse defect* (Fig. 24-12). Transverse defects are assessed

by replacing the anterior apical segment and observing if the prolapse descends during Valsalva maneuver. The urethra is also evaluated during anterior vaginal wall assessment, and Q-tip testing can be performed to determine urethral hypermobility (see Fig. 23-8).

Photograph shows a split speculum displacing the posterior vaginal wall. This allows for measurement of points Aa and Ba. Aa is always defined as a discrete point lying 3 cm proximal to the urethral meatus and is measured in relation to the hymen. During measurement, downward traction should be avoided, as this causes artificial descent of the anterior vaginal wall.

Photograph displays a transverse vaginal wall defect. Note detachment of the anterior vaginal wall from the apex and the presence of rugae, which suggests that this is not a midline or central defect.

The split speculum is then rotated 180 degrees to displace the anterior wall and allow examination of the posterior wall. Points Ap and Bp are measured (Fig. 24-13). If the posterior vaginal wall descends, attempts are made to determine if rectocele or enterocele is present. Enterocele can only definitively be diagnosed by observing small bowel peristalsis behind the vaginal wall (Fig. 24-14). In general, bulges at the apical segment of the posterior vaginal wall should implicate enteroceles, whereas bulges in the distal posterior wall are presumed to be rectoceles. Further distinction may be found during standing rectovaginal examination. A clinician's index finger is placed in the rectum and thumb on the posterior vaginal wall. Small bowel may be palpated between the rectum and vagina, confirming enterocele.

FIGURE 24-13

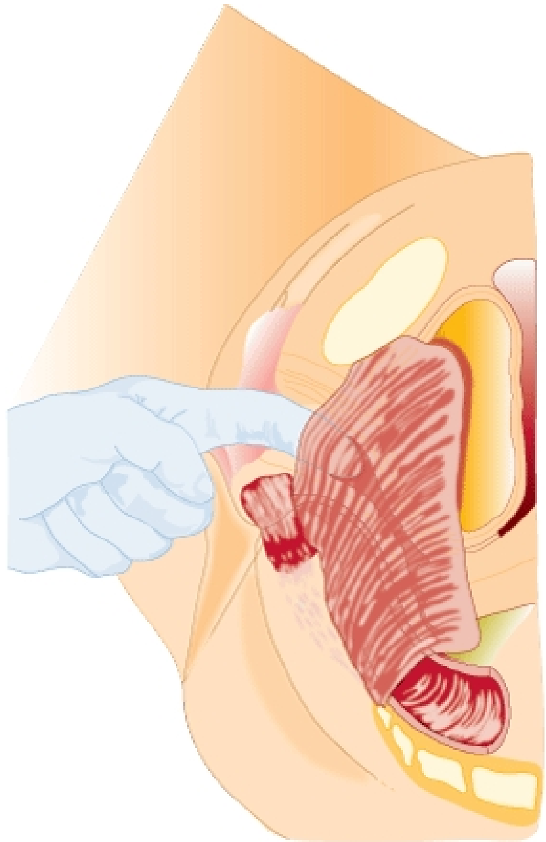
Photograph of enterocele. During evaluation, small bowel peristalsis may be noted behind the vaginal wall. Enterocele is most commonly noted at the vaginal apex, although anterior and posterior vaginal wall enteroceles may occur.

Overall, defect evaluation by vaginal examination has not been shown to have good inter- or intra-examiner reliability. However, individual evaluation may help assess prolapse severity and clarify anatomy if surgical correction is planned (Barber, 1999; Whiteside, 2004).

Bimanual examination is performed to identify other pelvic pathology. In addition, we strongly recommend assessment of pelvic floor musculature (Fig. 24-15). This examination is essential if pelvic floor rehabilitation is being considered as treatment. During evaluation, an index finger is placed 2 to 3 cm inside the hymen, at 4 and then 8 o'clock. Muscle resting tone and strength is assessed using the 0 through 5 Oxford grading scale. Five represents strong tone and strength (Laycock, 2002). Muscle symmetry is also evaluated. Asymmetric muscles, with palpable defects or scarring, may be associated with a prior obstetric forceps delivery or laceration.

FIGURE 24-15



Drawing depicts assessment of pelvic floor muscle assessment. The index finger is placed 2 to 3 cm inside the hymen at 4 and 8 o'clock. Both resting and contraction tone and strength are evaluated. *(From Toglia, 2003, with permission.)*

APPROACH TO TREATMENT

For women who are asymptomatic or mildly symptomatic, expectant management is appropriate. However, for women with significant prolapse or for those with bothersome symptoms, nonsurgical or surgical therapy may be selected. Treatment choice depends on the type and severity of symptoms, age and medical co-morbidities, desire for future sexual function and/or fertility, and risk factors for recurrence. Treatment should strive to provide symptom relief, but therapy benefits should always outweigh risks.

Often a combination of nonsurgical and surgical approaches may be selected. Symptoms should be ranked by severity and bother, and options for each should be discussed. An evidence-based appraisal of each option's success rate should be included. In the simplest case, a patient with prolapse of the vaginal apex beyond the hymen, whose only symptom is bulge or pelvic pressure, could be offered pessary or surgical treatment. In a more complicated case, a woman with prolapse beyond the hymenal ring may note a bulge, constipation, urge incontinence, and pelvic pain. Symptoms would be ranked as to severity of symptoms and importance of resolution. To address all complaints, therapy might involve pessary or surgery for bulge symptoms, as well as nonsurgical treatment of constipation, urge incontinence, and pelvic pain.

Nonsurgical Treatment

PESSARY USE IN PELVIC ORGAN PROLAPSE

Pessaries are the standard nonsurgical treatment for POP. Throughout history, various vaginal devices and materials for prolapse have been described, including cloth, wood, wax, metal, ivory, bone, sponge, and cork. Today's pessaries are usually made of silicone or inert plastic, and they are safe and simple to manage. Despite a long history of use, literature describing their indications, selection, and management is often anecdotal or contradictory.

Indications for Use

Pelvic organ prolapse is still the most common indication for vaginal pessary. Traditionally, pessaries have been reserved for women either unfit or unwilling to undergo surgery. A survey of the American Urogynecologic Society membership confirmed this sentiment among gynecologists with greater than 20 years in practice (Cundiff, 2000). However, the same survey showed that younger gynecologists, particularly those who described themselves as urogynecologists, used pessaries as a first-line therapy before recommending surgery. Women who have undergone at least one previous attempt at surgical management without relief may often choose a pessary over additional surgery.

Pessaries may also be used diagnostically. As previously discussed, symptoms may not correlate with the type or severity of prolapse. Short-term pessary use may be helpful in this process. Even if a patient declines long-term pessary use, she may agree to a short trial to determine if her chief complaint is improved or resolved. A pessary may also be placed diagnostically to identify which women are at risk for urinary incontinence after prolapse-correcting surgery (Chaikin, 2000; Liang, 2004).

A recent multicenter randomized cross-over trial compared two pessary types for relief of prolapse symptoms and urinary complaints. This study demonstrated that pessaries provide a modest improvement in urinary obstructive, irritative, and stress symptoms (Schaffer, 2006) (see Chap. 23, Pessary and Urethral Inserts).

Types of Pessaries

Two broad categories of pessaries exist: support and space-filling pessaries (Fig. 24-16). Support pessaries, such as the ring pessary, use a spring mechanism that rests in the posterior fornix and against the posterior aspect of the symphysis pubis. Vaginal support results from elevation of the superior vagina by the spring, which is supported by the symphysis pubis. Ring pessaries may be constructed as a simple circular ring or as a ring with support that looks like a large contraceptive diaphragm (Fig. 24-17). These are effective in women with first- and second-degree prolapse, and the support ring's diaphragm is especially useful in women with accompanying anterior vaginal wall prolapse. When properly fitted, the device should lie behind the pubic symphysis anteriorly and behind the cervix posteriorly.

Ring pessary with support. *(Courtesy of Milex, Cooper Surgical.)*

In contrast, space-filling pessaries maintain their position by creating suction between the pessary and vaginal walls (cube), by creating a diameter larger than the genital hiatus (donut), or by both mechanisms (Gellhorn). The Gellhorn is often used for moderate to severe prolapse and for complete procidentia (Fig. 24-18). It contains a concave disk that fits against the cervix or vaginal cuff and has a stem that is positioned just cephalad to the introitus. The concave disk supports the vaginal apex by creating suction, and the stem is useful for device removal. Of all pessaries, the two most commonly used and studied devices are the ring and Gellhorn pessaries.

Patient Evaluation and Pessary Placement

A patient must be an active participant in the treatment decision to use a pessary. Its success will depend upon her ability to care for the pessaryâ€”either alone or with the assistance of a caretakerâ€—and her willingness and availability to come for subsequent evaluations. Vaginal atrophy should be treated before or concomitantly with pessary initiation. The type of device selected may be affected by patient factors such as hormonal status, sexual activity, prior hysterectomy, and stage and site of POP. After a pessary is selected, a woman should be fitted with the largest size that can be comfortably worn. If a pessary is ideally fitted, a patient is not aware of its presence. As a woman ages and gains or loses weight, alternate sizes may be required.

Generally, a patient is fitted with a pessary while in the lithotomy position after she has emptied both her bladder and rectum. A digital examination is performed to assess vaginal length and width, and an initial estimation of pessary size is made. To introduce a ring pessary, the device is held in the clinician's dominant hand in a folded position (Fig. 24-18). Lubricant is placed on either the vaginal introitus or the pessary's leading edge. While holding the labia apart, the pessary is inserted by pushing in an inferior, cephalad direction against the posterior vaginal wall. Next, an index finger is directed into the posterior vaginal fornix to ensure that the cervix is resting above the pessary. The clinician's finger should barely slide between the lateral edges of the ring pessary and the vaginal sidewall.

Following pessary placement, a woman is prompted to perform a Valsalva maneuver, which might dislodge an improperly fitted pessary. She should be able to stand, walk, cough, and urinate without difficulty or discomfort. Instruction on removal and placement should then follow. For removal of a ring pessary, an index finger is inserted into the vagina to hook the ring's leading

edge. Traction is applied along the vaginal axis to bring the ring toward the introitus. Here it may be grasped by the thumb and index finger and removed.

Ideally, a pessary is removed nightly to weekly, washed in soap and water, and replaced the next morning. Women are sent home from their initial fitting session with instructions describing the management of commonly encountered problems (Table 24-7). After initial placement, a return visit may follow in 1 to 2 weeks. For patients comfortable with their pessary management, return visits may be semiannual. For those unable or unwilling to remove and replace a device themselves, a pessary may be removed and the patient's vagina inspected at the provider's office every 3 months. Scheduling of subsequent visits is individualized.

Table 24-7 Guidelines for Pessary Care

Pessary type__________
Size__________

1. After your initial pessary fitting is successful, you will be asked to return for a follow-up appointment in about 2 weeks. The purpose of this visit is to check the pessary and examine the vagina to ensure that it is healthy. Follow-up appointments will follow this schedule:
   1st year: every 3–6 months
   2nd year and beyond: every 6 months
   You may learn to care for the pessary yourself. For those patients who can remove and insert the pessary themselves, we recommend weekly overnight removal and cleansing of the pessary with soap and warm water. These patients should see the doctor at least once per year.
2. The following is a list of problems you may encounter with the pessary and our recommendations for their management.

Problem	Management
A. The pessary falls out.	Keep the pessary and notify your doctor's office. An appointment will be made. It may be possible that a change in the size or the type of pessary is needed.
B. You experience pelvic pain.	Notify your doctor's office. If the pessary has slipped and you can remove it, do so. Otherwise, have your doctor remove the pessary. A change in pessary size or type may be needed.
C. Vaginal discharge and odor.	You can douche with warm water and you may want to try using Trimo-San vaginal gel 1–3 times a week.
D. Vaginal bleeding.	Vaginal bleeding may be a sign that the pessary is irritating the lining of the vagina. Call your doctor's office and arrange an appointment.
E. Leaking from the bladder.	Sometimes, the support provided by the pessary will cause leaking from the bladder. Notify your doctor and discuss this problem.

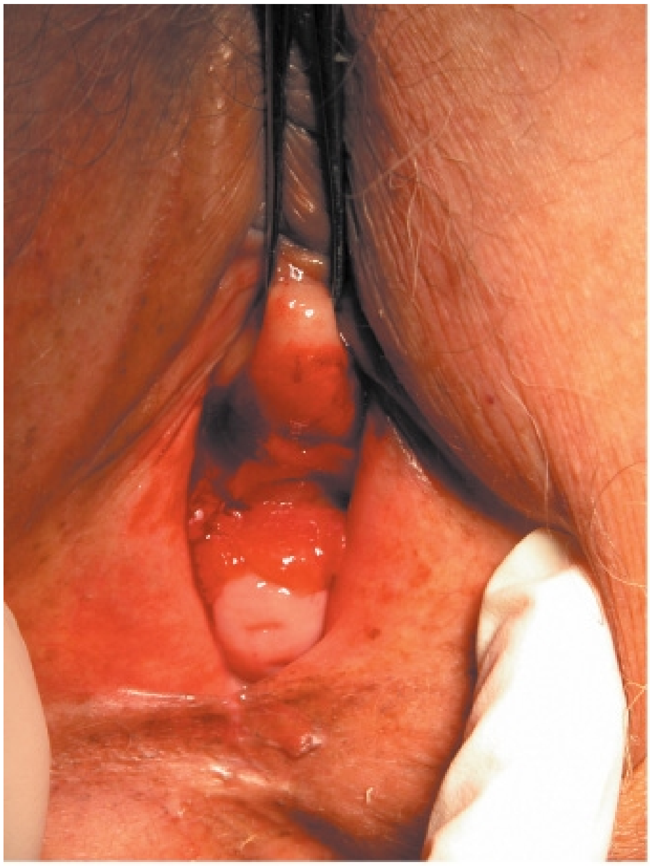
Trimo-San (Oxyquinolone, Milex Products, Chicago, IL) helps restore and maintain the normal vaginal acidity that helps reduce odor-causing bacteria.s

From Farrell, 1997, with permission.

Complications with Pessary Use

Serious complications such as erosions into adjacent organs are rare with proper use and usually result only after years of neglect. At each return visit, the pessary is removed and the vagina is inspected for erosions, abrasions, ulcerations, or granulation tissue (Fig. 24-19). Vaginal bleeding is usually an early sign and should not be ignored. *Pessary ulcers* or abrasions are treated by changing the pessary type or size to alleviate pressure points or by removing the pessary completely until healing occurs. *Prolapse ulcers* have the same appearance as pessary ulcers, however, they result from the prolapsed bulge rubbing on a patient's clothes. These are treated by placing a pessary. Treatment of vaginal atrophy with local or systemic estrogen is commonly required. Alternatively, water-based lubricants applied to the pessary may help prevent these complications.

FIGURE 24-19



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph shows granulation tissue involving the anterior and posterior vaginal wall resulting from pessary trauma.

Pelvic pain with pessary use is not normal. This usually indicates that the size is too large and is an indication for substituting a smaller-sized pessary. All pessaries tend to trap vaginal secretions and obstruct normal drainage to some degree. The resultant odor may be managed by encouraging more frequent nighttime device removal, washing, and re-insertion the next day. Alternatively, a woman may use Trimo-San gel (Milex Products, Chicago, IL) once or twice weekly or may douche with warm water. Trimo-San gel helps restore and maintain normal vaginal acidity that aids in reducing odor-causing bacteria.

PELVIC FLOOR MUSCLE EXERCISE

Pelvic floor muscle exercise has been suggested as a therapy that might limit progression and alleviate prolapse symptoms. Also known as Kegel exercises, these muscle-strengthening techniques are described in Chapter 23, Pelvic Floor Strengthening Exercises. There are two hypotheses that describe the benefits of pelvic floor muscle exercise for prolapse prevention and treatment (BÃ¸, 2004). First, from these exercises, women learn to consciously contract muscles before and during increases in abdominal pressure, which prevents organ descent. Alternatively, regular muscle strength training builds permanent muscle volume and structural support.

Unfortunately, there is no high-quality scientific evidence supporting pelvic exercise for prevention and treatment of prolapse (Hagen, 2004). However, pelvic floor exercise has minimal risk and low cost. For this reason, it may be offered to asymptomatic or mildly symptomatic women who are interested in prevention of progression and who decline other treatments.

SURGICAL TREATMENT

Obliterative Procedures

The two approaches to prolapse surgery are obliterative and reconstructive. The obliterative approach includes Lefort colpocleisis and complete colpocleisis (see Sections 42-23, Lefort Partial Colpocleisis and 42-24, Complete Colpocleisis). These procedures involve removing extensive vaginal epithelium, suturing anterior and posterior vaginal walls together, obliterating the vaginal vault, and effectively closing the vagina. Obliterative procedures are only appropriate for elderly or medically compromised patients, who have no future desire for coital activity.

Obliterative procedures are technically easier, require less operative time, and offer superior success rates compared with reconstructive procedures. Success rates for colpocleisis range from 91 to 100 percent, although the quality of evidence-based studies supporting these rates is poor (FitzGerald, 2006). Less than 10 percent of patients express regret after colpocleisis, often due to loss of coital activity (FitzGerald, 2006; Wheeler, 2005). Latent stress urinary incontinence can be unmasked with colpocleisis due to downward traction on the urethra.

Reconstructive Procedures

These surgeries attempt to restore normal pelvic anatomy and are more commonly performed than obliterative procedures for POP. Vaginal, abdominal, and laparoscopic approaches may be used and selection is individualized. However, in the United States, a vaginal approach is preferred by most for prolapse repair (Boyles, 2003; Brown, 2002; Brubaker, 2005a; Olsen, 1997).

The decision to proceed with a vaginal or abdominal approach depends on multiple factors including the patient's unique characteristics and surgeon's expertise. In certain instances, an abdominal approach appears to have clear advantages (Benson, 1996; Maher, 2004a, 2004b). These include women with prior failure of a vaginal approach, a shortened vagina, or those believed to be at higher risk for recurrence, such as young women with severe prolapse. In contrast, a vaginal approach typically offers shorter operative time and a quicker return to daily activities.

LAPAROSCOPY

A laparoscopic approach to prolapse is currently being used by experienced laparoscopic surgeons. Procedures include sacrocolpopexy, uterosacral ligament vaginal vault suspension, paravaginal repair, enterocele repair, and rectocele repair. In addition, robotic laparoscopic sacrocolpopexy is currently performed in centers with the da Vinci Robot (Intuitive Surgical, Sunnyvale, CA), and this has potential to decrease operative time.

Outcome studies of laparoscopic pelvic reconstruction, however, are mostly limited to case series (Higgs, 2005). Comparing laparoscopic and open approaches without randomized trials is difficult. However, surgeons with advanced laparoscopic skills who can perform the same operation laparoscopically should have equivalent results.

SURGICAL PLAN

Reconstructive prolapse repair will often involve a combination of procedures in several vaginal compartments. However, the decision regarding which compartments to repair is not always straightforward. In the past, a defect-directed approach to prolapse repair was preferred. With this approach, it was believed that all current, latent, or potential compensatory defects should be evaluated and repaired. However, current expert opinion suggests that asymptomatic areas of prolapse do not always warrant repair, and in fact, correction can lead to de novo symptoms. For instance, repair of an asymptomatic posterior wall prolapse may lead to dyspareunia. Thus, surgery should be designed to relieve *current* symptoms.

ANTERIOR COMPARTMENT

Many procedures for anterior vaginal wall prolapse repair have been described. Historically, anterior colporrhaphy has been the most common operation, yet long-term success rates are poor. In a randomized trial of three anterior colporrhaphy techniques (traditional midline plication, ultralateral repair, and traditional plication plus lateral reinforcement with synthetic mesh), Weber and colleagues (2001b) found a low rate of anatomic success. Satisfactory anatomic results were obtained in only 30 percent of the traditional group, 46 percent of the ultralateral group, and 42 percent of the traditional plus mesh group. These differences were not statistically significant. Although still frequently performed, the poor rates of anatomic success with traditional anterior

colporrhaphy have prompted re-evaluation of repair concepts and development of other procedures.

Despite these limitations, if a central or midline defect is suspected, anterior colporrhaphy may be performed (see Section 42-13, Anterior Colporrhaphy). Mesh or biomaterial may also be used in conjunction with anterior colporrhaphy or by itself. The mesh is used to reinforce the vaginal wall and is sutured in place laterally. However, the use of mesh and mesh kits for anterior vaginal wall prolapse has not been well studied and should be considered experimental (American College of Obstetricians and Gynecologists, 2007).

In many cases, anterior vaginal wall prolapse results from fibromuscular defects at the anterior apical segment or transverse detachment of the anterior apical segment from the vaginal apex. In these situations, an apical suspension procedure such as an abdominal sacrocolpopexy or uterosacral ligament vaginal vault suspension will resuspend the anterior vaginal wall to the apex and reduce anterior wall prolapse (see Sections 42-17, Abdominal Sacrocolpopexy and 42-18, Abdominal Uterosacral Ligament Suspension). Continuity is also re-established between the anterior and posterior vaginal fibromuscular layers to prevent enterocele formation.

Alternatively, if a lateral defect is suspected, paravaginal repair can be performed through the vaginal, abdominal, or laparoscopic route (see Section 42-14, Abdominal Paravaginal Defect Repair). Paravaginal repair is performed by re-attaching the fibromuscular layer of the vaginal wall to the arcus tendineus fascia pelvis.

VAGINAL APEX

There is a growing appreciation that support of the vaginal apex provides the cornerstone for a successful prolapse repair. Some experts believe that isolated surgical repair of the anterior and posterior walls is doomed for failure if the apex is not adequately supported (Brubaker, 2005b).

The vaginal apex can be resuspended with a number of procedures including abdominal sacrocolpopexy, sacrospinous ligament fixation, or uterosacral ligament vaginal vault suspension.

Abdominal Sacrocolpopexy

This surgery suspends the vaginal vault to the sacrum using synthetic mesh. Primary advantages include durability and conservation of normal vaginal anatomy. For example, compared with other vault suspension procedures, abdominal sacrocolpopexy offers greater vaginal apex mobility and avoids vaginal shortening. In addition, abdominal sacrocolpopexy provides enduring correction of apical prolapse, and long-term success rates approximate 90 percent. This procedure may be used primarily or as a second surgery for women with recurrences after failure of otherprolapse repairs.

Sacrospinous Ligament Fixation

This is one of the most popular procedures for apical suspension. The vaginal apex is suspended to the sacrospinous ligament unilaterally or bilaterally using a vaginal extraperitoneal approach. After SSLF, recurrent apical prolapse is uncommon, however, anterior vaginal wall prolapse develops postoperatively in 6 to 28 percent of patients (Benson, 1996; Morley, 1988; Paraiso, 1996). Complications associated with sacrospinous ligament fixation (SSLF) include buttock pain in 3 percent of patients and vascular injury in, 1 percent (Sze, 1997a, 1997b). Although uncommon, significant and life-threatening hemorrhage can follow injury to blood vessels located behind the sacrospinous ligament (see Section 42-20, Sacrospinous Ligament Fixation).

Uterosacral Ligament Vaginal Vault Suspension

With this procedure, the vaginal apex is attached to remnants of the uterosacral ligament at the level of the ischial spines or higher (see Section 42-19, Vaginal Uterosacral Ligament Suspension). Performed vaginally or abdominally, the uterosacral ligament vaginal vault suspension is believed to replace the vaginal apex to a more anatomic position than SSLF, which deflects the vagina posteriorly (Barber, 2000; Maher, 2004b; Shull, 2000).

This procedure has been adopted by many surgeons in the United States in attempts to reduce the rates of anterior vaginal prolapse recurrence following SSLF (Shull, 2000). Although uterosacral ligament vaginal vault suspension has gained wide popularity, studies supporting its use are limited to retrospective case series (Amundsen, 2003; Karram, 2001; Silva, 2006). In these studies and others, anterior vaginal prolapse recurrence rates range from 1 to 7 percent, and overall recurrence, from 4 to 18

percent.

HYSTERECTOMY AT THE TIME OF PROLAPSE REPAIR

In the United States, hysterectomy is often performed concurrently with prolapse surgery. Conversely, in many European countries, it is rarely performed during pelvic floor reconstruction. Although arguments exist for both, comparison has not been performed in randomized prospective trials.

If apical or uterine prolapse is present, hysterectomy will more readily allow the vaginal apex to be resuspended with the previously described apical suspension procedures. If hysterectomy is not performed in the context of apical prolapse, these procedures must be modified or specific uterine suspension procedures performed (not described in this text). Alternatively, if apical or cervical prolapse is not present, hysterectomy need not be incorporated into prolapse repair.

POSTERIOR COMPARTMENT

Enterocele Repair

Posterior vaginal wall prolapse may be due to enterocele or rectocele. Enterocele is defined as herniation of the small bowel through the vaginal fibromuscular layer, usually at the vaginal apex. Discontinuity of the anterior or posterior vaginal wall fibromuscular layers allows for this herniation. Accordingly, enterocele repairs have as their goal re-attachment of the fibromuscular layers. If posterior wall prolapse is due to enterocele, repair of this defect should reduce the posterior wall prolapse.

Rectocele Repair

Posterior vaginal wall prolapse due to rectocele is repaired with one of several techniques. Traditional posterior colporrhaphy aims to rebuild the fibromuscular layer between the rectum and vagina by performing a midline fibromuscular plication (see Section 42-15, Posterior Colporrhaphy). The anatomic cure rate is 76 to 96 percent, and most studies report a greater than 75-percent improvement rate of bulge symptoms (Cundiff, 2004). To narrow the genital hiatus and prevent recurrence, some surgeons plicate the levator ani muscles concurrently with posterior repair. However, this practice may contribute to dyspareunia rates of 12 to 27 percent (Kahn, 1997; Mellegren, 1995; Weber, 2000). Thus, it is best avoided in women who are sexually active.

Site-Specific Posterior Repair

This approach to posterior vaginal wall prolapse was first described by Richardson in 1993. This repair is based on the assumption that specific tears exist in the fibromuscular layer, which can be identified and repaired in a discrete fashion (see Section 42-15, Posterior Colporrhaphy). Defects may be midline, lateral, distal, or superior (Fig. 24-20). This approach is conceptually analogous to a fascial hernia, in which the fascial tear is identified and repaired. Thus, its theoretical advantage lies in its restoration of normal anatomy rather than plication of tissue in the midline.

FIGURE 24-20

Drawing depicts posterior vaginal wall defects. These may be midline, lateral, distal, or apical. (*From Richardson, 1993, with permission.*)

Site-specific repair has gained wide acceptance, however, anatomic cure rates range from 56 to 100 percent, similar to that with traditional posterior colporrhaphy (Muir, 2007). Moreover, anatomic and functional long-term outcomes are not known.

Mesh Reinforcement

In an effort to reduce prolapse recurrence, graft augmentation with allograft, xenograft, or synthetic mesh, has been used in conjunction with posterior colporrhaphy and site-specific repair. Generally, the graft is placed after colporrhaphy or site-specific repair is completed. Moreover, in situations in which the fibromuscular layer cannot be identified to perform a midline plication or site-specific repair, graft augmentation may be the only surgical option.

Mesh is sutured in place laterally with a minimum number of sutures. If technically possible, the graft is attached to the vaginal apex and the uterosacral ligament. Distally, the graft is attached to the perineal body.

The efficacy and safety of graft augmentation in the posterior vaginal wall has not been established. Paraiso and co-workers (2006) randomized 105 women to posterior colporrhaphy, site-specific repair, or site-specific repair plus porcine small intestine submucosa graft. After 1 year, those with graft augmentation had a significantly higher anatomic failure rate (46 percent) than those who received site-specific repair alone (22 percent) or posterior colporrhaphy (14 percent). More research is needed to determine the safety, efficacy, and optimal material for posterior wall graft augmentation.

Sacrocolpoperineopexy

This modification of sacrocolpopexy may be selected for correction of posterior vaginal wall descent when an abdominal approach is employed for other prolapse procedures or if treatment of perineal descent is necessary (Cundiff, 1997; Lyons, 1997; Sullivan,

2001; Visco, 2001). With this procedure, the posterior sacrocolpopexy mesh is extended down the posterior vaginal wall to the perineal body (see Fig. 42-15.11). In several case series, anatomic cure rates were greater than 75 percent.

PERINEUM

The perineum provides distal support to the posterior vaginal wall and anterior rectal wall and anchors these structures to the pelvic floor. A disrupted perineal body will allow descent of the distal vagina and rectum and will contribute to a widened levator hiatus.

Perineorrhaphy is often done in conjunction with posterior repair to recreate normal anatomy (see Section 42-16, Perineorrhaphy). During surgery, the perineum is rebuilt through midline plication of the perineal muscles and connective tissue. Importantly, overly aggressive plication can narrow the introitus, create a posterior vaginal wall ridge, and lead to entry dyspareunia. However, in a woman who is not sexually active, high perineorrhaphy with intentional introital narrowing is believed to decrease the risk of posterior wall prolapse recurrence.

THE USE OF MESH AND MATERIALS IN RECONSTRUCTIVE PELVIC SURGERY

Mesh Indications

Approximately 30 percent of women undergoing surgery for prolapse will require a repeat operation for recurrence (Olsen, 1997). As such, there is a continuous effort to improve surgical procedures and outcomes.

Synthetic mesh for sacrocolpopexy and midurethral slings has been widely studied and is safe and effective. Mesh erosion occurs in a small percentage of cases, but can be managed with local estrogen therapy and limited vaginal excision. Rarely is excision of the entire mesh warranted. In an attempt to limit erosion rates, surgeons have used biologic material, including cadaveric fascia. However, high rates of prolapse recurrence are associated with this material (FitzGerald, 1999, 2004; Gregory, 2005). Therefore, synthetic mesh is recommended.

The use of biologic or synthetic grafts for other transvaginal reconstructive pelvic surgery has expanded rapidly in the absence of supporting long-term safety and efficacy data. Some surgeons routinely use graft augmentation, others never use it, and some use it only for limited indications. Selective use may include: (1) the need to bridge a space, (2) weak or absent connective tissue, (3) connective tissue disease, (4) high risk for recurrence (obesity, chronically increased intra-abdominal pressure, and young age), and (5) shortened vagina. High-quality scientific data are lacking to support the use of grafts for augmentation of transvaginal prolapse repairs. Accordingly, the American College of Obstetricians and Gynecologists (2007) considers this practice experimental, and women should consent to surgery with this understanding.

Mesh Material

Surgeons using grafts should be familiar with the different types and their characteristics. Biologic grafts may be autologous, allograft, or xenograft. *Autologous* grafts are harvested from another part of the body such as rectus abdominis fascia or fascia lata. Morbidity is low, but may include increased operative time, pain, hematoma, or weakened fascia at the harvest site. *Allografts* come from a human source other than the patient and include cadaveric fascia or cadaveric dermis. *Xenografts* are biologic tissue obtained from a source or species foreign to the patient such as porcine dermis, porcine small intestinal submucosa, or bovine pericardium. Biologic materials have varying biomechanical properties and, as noted earlier, are associated with high rates of prolapse recurrence. Thus, recommendations on the appropriate clinical situations for biologic material are limited.

Synthetic grafts are classified as types I to IV, based on pore size (Table 24-8 and Fig. 24-21) (Amid, 1997). Pore size is the most important property of synthetic mesh. Bacteria generally measure less than 1 μm, whereas granulocytes and macrophages are typically larger than 10 μm. Thus, a mesh with pore size <10 μm may allow bacterial but not macrophage infiltration, and predispose to infection. Accordingly, type I mesh has the lowest rate of infection compared with types II and III. Pore size is also the basis of tissue ingrowth, angiogenesis, flexibility, and strength. Pore sizes of 50 to 200 μm allow for superior tissue ingrowth and collagen infiltration, again favoring type I. Meshes are either monofilament or multifilament. Multifilament mesh has small intrafiber pores that can harbor bacteria, therefore, monofilament mesh is recommended. From these findings, consensus suggests that if synthetic mesh is used, type I monofilament is the best choice for reconstructive pelvic surgery.

Table 24-8 Types of Surgical Mesh.

Type I:	Macroporous. Pore size >75 µm (size required for infiltration by macrophages, fibroblasts, blood vessels in angiogenesis, and collagen fibers) *GyneMesh, Atrium, Marlex, Prolene*
Type II:	Microporous. Pore size <10 µm in at least 1 dimension *Gore-Tex*
Type III:	Macroporous patch w/multifilaments or a microporous component *Teflon, Mersilene, Surgipro, Mycro Mesh*
Type IV:	Submicronic. Pore size <1 µm. Often used in association with type I mesh for intraperitoneal adhesion prevention *Silastic, Cellgard, Preclude*

Compiled from Amid, 1997.

Graft augmentation will undoubtedly persist due to the current poor cure rates with traditional transvaginal repairs. However, there is presently a paucity of evidence to guide the surgeon and provide a patient with accurate safety and efficacy information.

Moreover, industry-driven, premature adoption of untested materials and procedures has historically led to unacceptable complications. For these reasons, randomized, prospective trials comparing traditional repairs with graft augmentation are urgently needed.

Concomitant Prolapse and Incontinence Surgery

Prior to prolapse surgery, women should be evaluated for stress urinary incontinence (SUI) (see Chap. 23, Symptom Clustering). Those with bothersome SUI symptoms should be considered for concurrent anti-incontinence surgery. However, in women without SUI symptoms, latent stress incontinence may be unmasked or SUI may develop de novo following prolapse repair. Therefore, preoperative urodynamic testing with the prolapse replaced is recommended. If stress incontinence is demonstrated, these patients also should be considered for a concurrent anti-incontinence operation. This has been a difficult decision for patients and surgeons because a procedure with known risks is being performed for a problem that does not currently exist and may never develop. However, the recent CARE (Colpopexy and Urinary Reduction Efforts) trial has shed new light on this problem (Brubaker, 2006). Women undergoing abdominal sacrocolpopexy for prolapse (anterior vaginal wall stage 2 or greater) who did not exhibit symptoms of stress incontinence were randomized to undergo concurrent Burch colposuspension or not. Preoperative urodynamic testing was performed but surgeons were blinded to the results. Three months after surgery, 24 percent of women in the Burch group and 44 percent of women in the control group met one or more criteria for stress incontinence. The incontinence was bothersome in 6 percent of the Burch group and 24 percent of the control group.

These data can be interpreted in several ways. It can be argued that all women undergoing sacrocolpopexy for stage 2 or greater anterior vaginal wall prolapse should undergo Burch colposuspension, as 44 percent will develop stress incontinence symptoms. However, the opposing argument is that only 24 percent will develop bothersome incontinence symptoms, thus three quarters of women would be subjected to an unnecessary operation.

Importantly, this study provides Level 1 evidence for a surgeon to share during patient counseling. The authors of this study caution that these data cannot be extrapolated to other prolapse and incontinence surgeries. However, in lieu of other Level 1 evidence, surgeons can still use this information in surgical planning and presurgical patient discussions.

CONCLUSION

Pelvic organ prolapse is a significant health concern for women. Evaluation should focus on symptoms, their anatomic correlation, and their effect on patient quality of life. Nonsurgical and surgical therapy should be symptom-based and should be undertaken with a realistic, evidence-based assessment of outcomes.

Current research is focused on improving treatment outcomes. In the future, a greater knowledge of modifiable risk factors such as events surrounding pregnancy and delivery, may allow improved opportunities for prevention.

ANAL INCONTINENCE

Anal incontinence (AI) is an involuntary loss of flatus, liquid, or solid stool that causes a social or hygienic problem (Abrams, 2005). This condition may lead to poor self-image and social isolation, thus significantly impairing quality of life (Johanson, 1996; Perry, 2002). Additionally, AI creates a substantial financial burden to patients and the health care system (Whitehead, 2001).

The definition of AI includes incontinence of flatus, whereas that of *fecal incontinence* (FI) does not. Not included in either definition is *anal mucoid seepage* . This type of fecal leakage develops in those with a fully functional anal sphincter and intact cognition. It most often is associated with organic colonic disease or dietary sensitivity (Abrams, 2005).

Epidemiology

Anal incontinence is common and affects all age groups. In contrast to previous beliefs, it affects men and women similarly (Madoff, 2004; Nelson, 2004). In a recent systematic review of the literature, Macmillan and co-workers (2004) reported that the estimated prevalence of AI among community-dwelling adults ranges between 2 and 24 percent if flatal incontinence is included, and between 0.4 and 18 percent if flatal incontinence is not (Macmillan, 2004). Wide variations are attributed to differences in definition, lack of validated tools, and surveyed cohort's age. In a multicenter trial that included seven geographically distinct sites in the United States, Boreham and co-workers (2005) reported the prevalence, risk factors, and impact upon quality of life of AI in women aged 18 to 65 years presenting for benign gynecologic care. The overall prevalence of AI in this cohort was 28 percent. The prevalence of AI increases with age, and has been reported to reach 46 percent in older, institutionalized women (Nelson, 1998).

Pathophysiology of Defecation and Anal Continence

Normal defecation and anal continence are complex processes that require a competent anal sphincter complex, normal anorectal sensation, adequate rectal capacity and compliance, and conscious control.

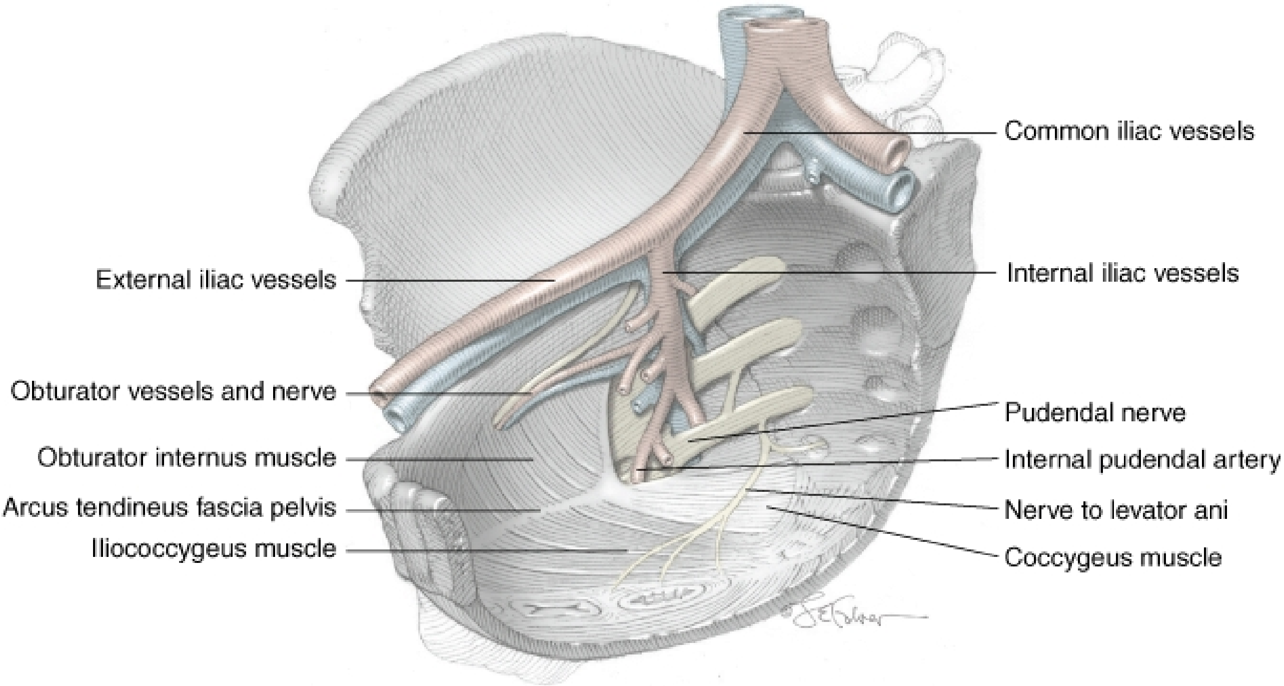
ANAL SPHINCTER COMPLEX

This neuromuscular complex consists of the internal and external anal sphincter muscles and the puborectalis muscle (see Fig. 38-21). Of these, the internal anal sphincter (IAS) is the thickened distal 3- to 4-cm longitudinal extension of the colon's circular smooth muscle layer. It is innervated by the autonomic nervous system and provides 70 to 85 percent of the anal canal's resting pressure (Frenckner, 1975). As a result, the IAS contributes substantially to the maintenance of fecal continence at rest.

The external anal sphincter (EAS) consists of striated muscle and is primarily innervated by somatic motor fibers that course in the inferior rectal branch of the pudendal nerve (see Fig. 38-28). The EAS provides the anal canal's *squeeze pressure* and is mainly responsible for maintaining fecal continence when continence is threatened. At times, squeeze pressure may be voluntary or may be induced by increased intra-abdominal pressure. In addition, although resting sphincter tone is generally attributed to the IAS, the EAS maintains a constant state of resting contraction and may be responsible for approximately 25 percent of anal resting pressure. During defecation, however, the EAS relaxes to allow stool passage.

The puborectalis muscle is part of the levator ani muscle complex and is innervated from its pelvic surface by direct efferents from the third, fourth, and fifth sacral nerve roots (Fig. 25-1) (Barber, 2002). Its constant tone contributes to the anorectal angle, which aids in preventing rectal contents from entering the anus (see Fig. 38-9). Similar to the EAS, this muscle can be contracted voluntarily or in response to sudden increases in abdominal pressure.

FIGURE 25-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Innervation of the female pelvic floor muscles from direct branches of S3 through S5.

The role of the puborectalis in maintaining stool continence remains controversial. However, it is best appreciated in women who remain continent of solid stool despite absence of the anterior portion of the external and internal sphincters, as can be seen in those with chronic fourth-degree lacerations (Fig. 25-2). With normal functioning of this muscle, evacuation is generally associated with a greater (or less obtuse) anorectal angle as the puborectalis relaxes. Conversely, paradoxical contraction of the puborectalis muscle during defecation may lead to impaired evacuation. Moreover, atrophy of this muscle has been associated with fecal incontinence (Bharucha, 2004).

FIGURE 25-2

Chronic fourth degree laceration with complete absence of the perineal body and anterior portion of external anal sphincter (cloacal deformity). Skin dimples at 3 and 9 o'clock (**arrows**) indicate site of retracted ends of external anal sphincter.

ANORECTAL SENSATION

Anorectal Innervation

Innervation to the rectum and anal canal is derived from the superior, middle, and inferior rectal autonomic nerve plexuses that contain sympathetic and parasympathetic components, and by intrinsic nerves present in the rectoanal wall. In addition, the inferior rectal branch of the pudendal nerve conveys sensory input from the lower anal canal and the skin around the anus (see Fig. 38-30). Sensory receptors within the anal canal and pelvic floor muscles can detect the presence of stool in the rectum as well as the degree of distention. Through these neural pathways, information regarding rectal distension and rectal contents can be transmitted and processed and the action of the sphincteric musculature coordinated.

Rectoanal Inhibitory Reflex

The *rectoanal inhibitory reflex* (RAIR) refers to the transient relaxation of the IAS and contraction of EAS induced by rectal distension when stool first arrives in the rectum. This reflex is mediated by the intrinsic nerves in the anorectal wall and allows the sensory rich upper anal canal to come in contact with or "sample"' the rectal contents (Whitehead, 1987). Specifically, *sampling* refers to the process whereby the internal anal sphincter (IAS) relaxes, often independently of rectal distension, allowing the anal epithelium to ascertain whether rectal contents are gas, liquid, or solid stools (Miller, 1988).

Following integration of this neural information, defecation can ensue in the appropriate social setting. Alternatively, if required,

defecation can generally be postponed, as the rectum can accommodate its contents, and the external anal sphincter (EAS) or puborectalis muscle or both can be voluntarily contracted. However, if rectal sensation is impaired, contents may enter the anal canal and may leak before the EAS can contract (Buser, 1986).

Evaluation of the RAIR may clarify the underlying etiology of AI. This reflex is absent in those with congenital aganglionosis (Hirschsprung's disease) but preserved in patients with cauda equina lesions or after spinal cord transection (Bharucha, 2006).

RECTAL ACCOMMODATION AND COMPLIANCE

Following anal sampling, the rectum can relax to admit the increased rectal volume in a process known as accommodation. The rectum is a highly compliant reservoir that aids storage of stool. As rectal volume increases, an urge to defecate is perceived. If this urge is voluntarily suppressed, the rectum relaxes to continue stool accommodation. A loss of compliance may decrease the ability of the rectal wall to stretch or accommodate, and as a result, rectal pressure may remain high. This may place increased demands on the other components of the continence mechanism such as the anal sphincter complex.

Rectal compliance can be calculated by measuring the sensitivity and maximal volume tolerated in a fluid-filled balloon during anorectal manometry (Anorectal Manometry). Rectal compliance may be decreased in those with ulcerative and radiation proctitis. In contrast, increased compliance may be noted in certain patients with constipation, potentially signaling a megarectum.

Incontinence Risks

Causes of AI and defecatory disorders are diverse and are likely multifactorial. These conditions develop if structural and/or functional components of continence and defecatory mechanisms are altered (Table 25-1).

Table 25-1 Risk Factors for Fecal Incontinence
Obstetric
Increasing parity
Anal sphincter damage
Other medical conditions
Increasing age
Increasing body mass index
Postmenopausal status
Diabetes
Chronic hypertension
Chronic obstructive pulmonary disease
Stroke
Scleroderma
Prior pelvic radiation therapy
Medications
Urogynecologic

Urinary incontinence
Pelvic organ prolapse
Gastrointestinal
Constipation
Diarrhea
Fecal urgency
Food intolerance
Irritable bowel syndrome
Prior anal abscess or fistula
Prior anal surgery
Neuropsychiatric
Spinal cord injury
Parkinson disease
Prior spinal surgery
Multiple sclerosis
Myopathies
Cognitive dysfunction
Psychosis

OBSTETRIC

In younger, reproductive-aged women, the most common association with AI is vaginal delivery and damage to the anal sphincter muscles (Snooks, 1985; Sultan, 1993; Zetterstrom, 1999). This damage may be mechanical or neuropathic and can result in early fecal and flatal incontinence.

Rates of sphincter tear during vaginal births in the United States range from 6 to 18 percent (Fenner, 2003; Handa, 2001). A recent multicenter trial conducted by the Pelvic Floor Disorders Network prospectively evaluated bowel continence status in primiparous women delivered at term in the United States. Their results showed that at both 6 weeks and 6 months postpartum, women who sustained anal sphincter tears during vaginal delivery had twice the risk of FI and reported more severe FI compared with women who delivered vaginally without evidence of sphincter disruption (Borello-France, 2006). In contrast, a retrospective study evaluated 151 women with diverse obstetric histories who delivered 30 years previously. Women with a prior sphincter disruption were more likely to have "bothersome"' flatal incontinence, but were not at increased risk for FI compared with women who had an isolated episiotomy or those who underwent cesarean delivery (Nygaard, 1997). Thus, other mechanisms associated with pregnancy and factors associated with aging may contribute to AI regardless of delivery mode.

OTHER FACTORS

Inflammatory bowel conditions and radiation therapy involving the rectum can result in poor compliance and loss of accommodation. Of these patients, those with inflammatory bowel disease and chronic diarrhea are more frequently affected. Liquid stool is more difficult to control than solid, and thus FI may develop in these women even if all components of the continence mechanism are grossly intact. Alternatively, chronic constipation with straining at stool may result in damage to the muscular and/or neural components of the sphincter mechanism. Similarly, other neuromuscular injury to the puborectalis and/or anal sphincter muscles, such as that associated with pelvic organ prolapse may lead to AI.

Nervous system dysfunction in those with spinal cord injury, back surgery, multiple sclerosis, diabetes, or cerebrovascular accident may lead to poor accommodation, loss of sensation, impaired reflexes, and myopathy. Finally, loss of rectal sensation can be seen with normal aging.

Diagnosis

Precise identification of the underlying cause and accurate assessment of symptom severity are essential prior to selecting an appropriate treatment plan. A complete history and physical examination should always be the first step in evaluating patients with AI, and often leads to identification of correctable problems. Following examination, anal endosonography is usually obtained to identify anal sphincter anatomic defects that may be amenable to surgery. Other selected tests, which are described below, may be added as clinically indicated. However, because current surgical outcomes are less than optimal, most patients, even those with anatomic defects, are initially treated conservatively.

HISTORY

A thorough history should include incontinence duration and frequency, stool consistency, timing of incontinent episodes, use of sanitary protection, and social impact of incontinence. Additionally, questioning should address risk factors noted in Table 25-1. Importantly, urge-related AI should be differentiated from incontinence without awareness, as these may be associated with different underlying pathologies. Additionally, urgency without incontinence may reflect inability of the rectal reservoir to store stool rather than a sphincteric disorder.

Validated Questionnaires

Several incontinence-scoring systems have been developed that provide objective measures of a patient's degree of incontinence. The fecal incontinence severity index (FISI) is a brief, validated instrument used to determine AI severity (Table 25-2) (Rockwood, 1999). In addition, the validated fecal incontinence quality of life (FIQL) questionnaire is designed to estimate the impact of fecal incontinence on lifestyle, coping behavior, depression/self-perception, and embarrassment (Table 25-3) (Rockwood, 2000). These validated questionnaires may be used diagnostically but also following treatment to determine response.

Table 25-2 Fecal Incontinence Severity Index

	Two or More Times Daily	Once Daily	Two or More Times Weekly	Once Weekly	1â€“3 Times Monthly	Never
Gas	☐	☐	☐	☐	☐	☐
Mucus	☐	☐	☐	☐	☐	☐
Liquid stool	☐	☐	☐	☐	☐	☐
Solid stool	☐	☐	☐	☐	☐	☐

Table 25-3 Fecal Incontinence Quality of Life Scale Composition

Scale 1: Lifestyle

- I cannot do many of the things I want to do
- I am afraid to go out
- It is important to plan my schedule (daily activities) around my bowel pattern
- I cut down on how much I eat before I go out
- It is difficult for me to get out and do things like going to a movie or to church
- I avoid traveling by plane or train
- I avoid traveling
- I avoid visiting friends
- I avoid going out to eat
- I avoid staying overnight away from home

Scale 2: Coping/Behavior

- I have sex less often than I would like to
- The possibility of bowel accidents is always on my mind
- I feel I have no control over my bowels
- Whenever I go someplace new, I specifically locate where the bathrooms are
- I worry about not being able to get to the toilet in time
- I worry about bowel accidents
- I try to prevent bowel accidents by staying very near a bathroom
- I can't hold my bowel movement long enough to get to the bathroom
- Whenever I am away from home, I try to stay near a restroom as much as possible

Scale 3: Depression/Self-perception

- In general, how would you say your health is
- I am afraid to have sex
- I feel different from other people
- I enjoy life less
- I feel like I am not a healthy person
- I feel depressed
- During the past month, have you felt so sad, discouraged, hopeless, or had so many problems that you wondered if anything was worthwhile

Scale 4: Embarrassment

- I leak stool without even knowing it
- I worry about others smelling stool on me
- I feel ashamed

Adapted from Rockwood, 2000, with permission.

PHYSICAL EXAMINATION

Examination should begin with careful inspection of the anus and perineum, looking for stool soiling, scars, perineal body length, hemorrhoids, anal warts, rectal prolapse, dovetail sign, or other anatomic abnormalities (Fig. 25-3). The perianal skin is gently stroked with a cotton-tipped swab, and the cutaneous anal reflex, also colloquially termed *anal wink,* should be noted. This finding provides gross assessment of pudendal nerve integrity.

FIGURE 25-3

Photograph showing the dovetail sign, which is created by disruption of the anterior portion of external anal sphincter (EAS). Radial skin spikes are typically formed by attachment of skin to the EAS, but are commonly absent from 10 to 2 o'clock* in those with this disruption.

With digital rectal examination, one can assess IAS resting tone, sample for gross or occult blood, and palpate masses or fecal impaction. In addition, squeeze pressure can subjectively be assessed during voluntary patient contraction of the EAS around a finger inserted into the rectum. Lastly, patients performing a Valsalva maneuver can allow inspection for excessive perineal body descent, vaginal wall prolapse, and rectal prolapse (Fig. 25-4).

FIGURE 25-4

Patient at rest **(A)** and with Valsalva **(B)** , showing full-thickness rectal prolapse protruding through the anal opening.

DIAGNOSTIC TESTING

Enema

A tap water enema is a simple test that may be used to determine if a patient is truly incontinent. Liquid stool is more difficult to control than solid stool, and thus patients who can hold enema contents for several minutes are not likely to have significant FI. In these instances, other etiologies for their symptoms should be sought.

Anorectal Manometry

During this test, a small flexible tube containing an inflatable balloon tip and pressure transducer is inserted into the rectum. Resting and squeeze pressures of the anal canal are then measured at incremental points as the balloon is slowly withdrawn from the rectum (Fig. 25-5). As an additional test, pressures may also be measured as a patient simulates defecation and expels the catheter balloon tip. In sum, anorectal manometry allows assessment of: (1) anal sphincter function, (2) reflexes, (3) rectal compliance, and (4) rectal sensation (Table 25-4).

Table 25-4 Functional Testing for Patients with Fecal Incontinence[a]

Factors of Relevance in FI	Manometry: Anal Resting Pressure	Manometry: Anal Squeeze Pressure	Manometry: Rectal Perception	Manometry: Rectal Compliance	Defecography	EAUS	E
Anal sphincters							
Internal	+					+	
External		+				+	+
Puborectalis					+		+
Rectum							
Perception			+				
Compliance				+			
Reservoir function			+	+	+		
Megarectum			+		+		
Pelvic floor							
Perineal descent					+		
Anorectal angle					+		
Neural							
Pudendal nerve		+					+

[a] A plus sign indicates an appropriate test for a particular component of continence.

EAUS = endoanal ultrasonography; EMG = electromyography; FI = fecal incontinence.

Manometry tube and balloon, empty **(A)** and after filling **(B)** .

During evaluation of the sphincters, manometry objectively measures IAS resting pressure and EAS squeeze pressure. Decreased pressure readings may indicate structural disruption, myopathy, or neuropathy.

Sphincter reflexes are also assessed during pressure measurements. During balloon insufflation, relaxation of the IAS should accompany rectal distention via the rectoanal inhibitory reflex (RAIR).

Rectal compliance and sensation may be determined by sequentially inflating a rectal balloon to various volumes. Decreased rectal compliance may be noted by an inability to inflate a balloon to typical volumes without patient discomfort. This may indicate a rectal reservoir that is unable to appropriately store stool. In contrast, decreased perception of balloon insufflation may indicate neuropathy.

One of the main limitations with manometry is that normal values may be seen in incontinent patients and vice versa. Despite this disadvantage, anal manometry serves an important role in the evaluation of AI.

Endoanal Ultrasonongraphy

Also known as, *transanal sonography,* this technique was introduced in 1989 and is now the primary diagnostic imaging technique to evaluate the integrity, thickness, and length of the internal and external anal sphincters (Fig. 25-6). This tool allows diagnosis of sphincter defects in women with occult defects from obstetric trauma who in the past were labeled as having "idiopathic"' FI and who may not have been considered for surgical correction. The technique uses a rotating endoprobe with a 10-MHz transducer, which provides a 360-degree evaluation of the anal canal.

FIGURE 25-6

A

Endoanal ultrasonography in a woman with normal anal sphincters **(A)** and anterior defects of the external and internal anal sphincter muscles **(B)** . **Dashed lines** and **arrows** in B illustrate the ends of the torn EAS. IAS = internal anal sphincter; EAS = external anal sphincter.

In addition, this modality can image the puborectalis muscle and perineal body. A recent study by Oberwalder and colleagues (2004) showed that in a group of incontinent women, perineal body thickness of less than or equal to 10 mm was associated with anal sphincter defects in 97 percent of cases. In contrast, perineal body thickness of 10 mm to 12 mm was associated with sphincter defects in one third of patients with FI. Perineal body thickness greater than 12 mm was infrequently associated with these defects.

Magnetic Resonance (MR) Imaging

Endoanal magnetic resonance (MR) imaging is typically done with an anal endocoil. This modality is more expensive than anal endosonography, and its value for anal sphincter evaluation is controversial. Although sonography has been shown to be more sensitive in detecting IAS abnormalities, MR imaging is more sensitive in visualizing EAS morphology including atrophy (Beets-Tan, 2001; Rociu, 1999). This may have value preoperatively, as patients with EAS atrophy may have poorer results following anal sphincteroplasty compared with those without atrophy (Briel, 1999). However, the role of endocoil MR imaging in the assessment of AI is yet to be determined. Recent evidence from a National Institutes of Health (NIH)-funded trial within the Pelvic Floor Disorders Network (PFDN) has challenged the reproducibility of MR imaging in detecting anal sphincter defects.

A second MR imaging modality, termed *dynamic MR imaging* allows dynamic examination of rectal emptying and evaluation of pelvic floor muscles, including the puborectalis muscle, during rest, squeeze, and defecation. It simultaneously permits pelvic organ prolapse assessment. This current research tool, however, is technically difficult and other than avoiding the ionizing radiation

associated with evacuation proctography, this technique offers no advantage for studying rectal function in the clinical setting.

Evacuation Proctography

During this radiographic test, also known as *defecography,* the rectum is opacified with a thick barium paste, and the small bowel fills with a barium suspension given orally. Radiographs or fluoroscopic imaging is then obtained while a patient is resting, contracting their sphincter, coughing, and straining to expel the barium.

This test of dynamic rectal emptying and anorectal anatomy is not widely used to assess evacuation disorders unless obstructive causes for AI are suspected. Accordingly, it may be obtained if intussusception, internal rectal prolapse, or enteroceles are concerns.

Electromyography

This test graphically records electrical activity of muscles at rest and during contraction. During electromyography (EMG), needle electrodes are inserted through the skin into a muscle, and electrical activity detected by these electrodes is displayed graphically. In evaluation of AI, EMG may be used to assess the neuromuscular integrity of the EAS and puborectalis muscle. Specifically, by measuring action potentials from muscle motor units, EMG can help clarify which portions of these muscles are contracting and relaxing appropriately. Additionally, following injury, muscle may be partially or completely denervated, and compensatory re-innervation may then follow. Patterns characteristic of such denervation and re-innervation may be identified with EMG.

Surface Electromyography

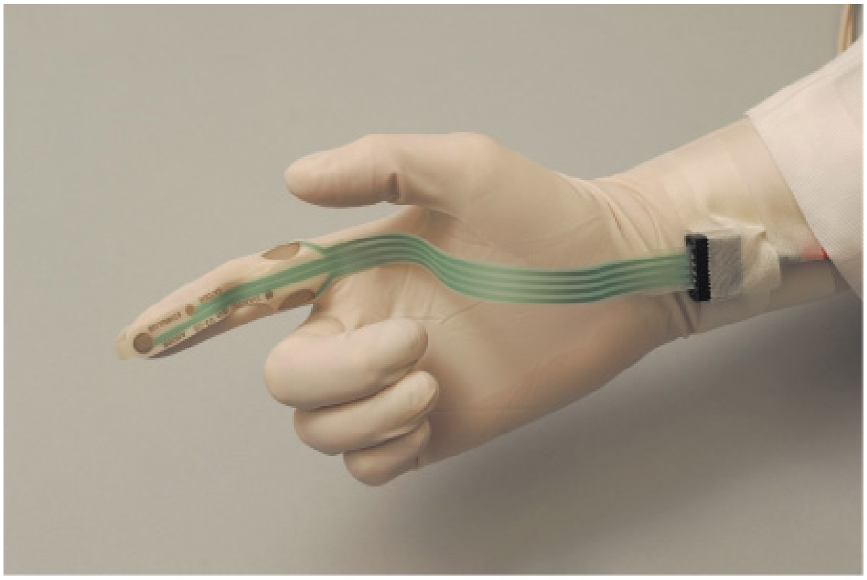
For EMG testing, concentric-needle, single-fiber, or surface EMG can be used. Needle EMG is primarily used in research, whereas surface EMG is most commonly used in clinical settings. Unlike needle electrodes, surface electrodes are placed next to the anus, cause little discomfort to the patient, and carry no risk of infection. This technique provides useful information regarding sphincter innervation and can be used during biofeedback to give visual or auditory signals to patients.

Pudendal Nerve Terminal Motor Latency Test

This stimulation test of the pudendal nerve measures the time delay between electrical nerve stimulation and EAS motor response. This delay, also termed *latency,* if prolonged, may indicate pudendal nerve pathology, which may be a cause of AI.

During pudendal nerve motor latency (PNML) testing, an electrode positioned on an examiner's fingertip is connected to a pulsed-stimulus generator (Fig. 25-7). The pudendal nerves are transanally stimulated through the lateral walls of the rectum at the level of the ischial spines. The action potential response of the EAS is received by an electrode at the base of the examining finger and registered on an oscilloscope.

FIGURE 25-7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pudendal nerve motor latency (PTML) electrode connected to an examiner's finger.

Although PNML prolongation has been considered a marker of idiopathic fecal incontinence, this test provides little information regarding the etiology of fecal incontinence. Accordingly, it has been replaced by more specific and sensitive tests for sphincter muscle innervation such as EMG (Barnett, 1999). However, in patients with a sphincter defect who are candidates for repair, general sphincter neurologic status can be assessed by this test, and the results used in preoperative counseling. For example, patients with pudendal neuropathy may have poorer outcomes after anatomic sphincter re-approximation compared with those without nerve dysfunction (Gilliland, 1998).

Colonoscopy and Barium Enema

Based on the history and physical examination, these tests may be indicated to exclude inflammatory bowel conditions or malignancy.

Treatment

The goal of treatment is to restore or improve fecal continence and improve patient quality of life. Treatment is highly individualized and dependent on the etiology and severity of AI, available treatment options, and patient health.

NONSURGICAL

Most patients with AI, excluding those with an obvious anal sphincter defect and significant FI, may benefit from conservative management. This may include diet modification, constipating agents, bulking agents, timed enemas or suppositories, and biofeedback.

Medical Management

A recent Cochrane review of randomized or quasi-randomized controlled trials analyzed the use of pharmacologic agents for the treatment of FI in adults. Of these trials, most focused on diarrheal treatment, rather than FI, and thus, limited data are available to guide clinicians in drug therapy selection (Cheetham, 2003). However, for patients with minor incontinence, the use of bulking agents can change stool consistency and create feces that are firmer and easier to control (Table 25-5). Common side effects such as abdominal distension and bloating can be improved by starting with smaller doses or switching to a different agent.

Table 25-5 Medical Management of Fecal Incontinence

Treatment	Brand Name	Oral Dosage	Manufacturer
Bulking agents			
Psyllium	Metamucil	1 tbsp. mixed into 8 oz. of water 1â€“3 times daily	Proctor and Gamble
Psyllium	Konsyl	1 tsp. mixed into 8 oz. of water 1â€“3 times daily	Konsyl Pharmaceuticals
Methycellulose	Citrucel	1 tbsp. mixed into 8 oz. of water 1â€“3 times daily	GlaxoSmithKline
Loperamide hydrochloride	Imodium	2â€“4 mg, 1â€“4 times daily to a maximum daily dose of 16 mg	McNeil PPC
Diphenoxylate hydrochloride	Lomotil	5 mg, 1â€“4 times daily to a maximum daily dose of 20 mg	Pfizer
Amitriptyline	Generic	10â€“25 mg at bedtime; increase by 10â€“25 mg weekly up to 75â€“150 mg at bedtime or a therapeutic drug level	

Agents that slow fecal intestinal transit time such as loperamide hydrochloride can reduce stool volume in patients with diarrhea and FI by increasing the time available for removal of fluid from stool. This agent has also been shown to increase anal resting tone, and therefore, may even be beneficial for patients with FI and no diarrhea (Read, 1982). Side effects are uncommon.

Diphenoxylate hydrochloride is used in the same capacity as loperamide hydrochloride and dosing is similar. Although this is a schedule V substance, the potential for physical dependence is minimal.

Finally, amitriptyline is a tricyclic antidepressant that has been used to treat idiopathic FI. Although the mechanism of action is poorly understood, some of its beneficial effects may be related to its anticholinergic properties.

Bowel Management

Daily, timed, tap water enemas or glycerin or bisacodyl suppositories (Dulcolax, Boehringer Ingelheim Pharmaceuticals, Ridgefield, CT) may be used to empty the rectum after eating. These provide acceptable and helpful options for some patients. Bulking agents can be used concurrently with these evacuation methods to diminish stooling between desired defecations.

Biofeedback and Pelvic Floor Therapy

Many behavioral techniques, often considered together as biofeedback, measure physiologic signals such as muscle tension and then display them to a patient in real time. In general, visual, auditory, and/or verbal feedback cues are directed to the patient during these therapy sessions. Thus, candidates typically include those whose cognitive function is intact, who can follow commands, and who are motivated.

Biofeedback is usually selected to increase neuromuscular conditioning. Specifically, for FI, goals of therapy are to improve anal sphincter strength, sensory awareness of stool presence, and coordination between the rectum and the anal sphincter (Rao, 1998). Treatment protocols are individualized and dictated by the underlying dysfunction. Accordingly, the number and frequency of sessions required for improvement varies but commonly three to six 1-hour, weekly or bi-weekly appointments are needed. In many cases, reinforcing sessions at various subsequent intervals are also recommended.

Biofeedback has been noted to be an effective treatment for FI, and symptomatic improvement has been reported in up to 80 percent of treated patients (Engel, 1974; Jensen, 1997; Norton, 2001). However, in a review of biofeedback and pelvic floor exercises for FI, Norton and colleagues (2001) found insufficient evidence to draw conclusions regarding the benefit of biofeedback

for FI. Despite this, a large number of studies have shown positive outcomes for biofeedback in treating FI. Biofeedback is a benign and relatively inexpensive treatment compared with other medical interventions. Accordingly, it is often used to treat these disorders.

Pelvic Floor Muscle Strengthening Exercises

Also known as *Kegel exercises,* this technique alone has not been definitively shown to benefit patients with FI (Whitehead, 1985). However, they are safe and free of cost and may benefit some patients, especially if performed in conjunction with other therapies. These exercises are described further in Chapter 23, Pelvic Floor Strengthening Exercises.

SURGICAL

Given the potential for postoperative morbidity and the less less-than than-optimal results presently reported with available surgical procedures, surgery should be reserved for those patients with major structural abnormalities of the anal sphincter(s), severe symptoms, and those who fail to respond to conservative management.

Anal Sphincteroplasty

Repair of the EAS and/or IAS is most commonly performed in patients with acquired AI and an anterior sphincter defect following an obstetric or iatrogenic injury. Two methods may be used for sphincter repair and include an end-to-end technique and an overlapping method (see Section 42-25, Anal Sphincteroplasty). The end-to-end technique is most commonly used by obstetricians to re-approximate torn ends of an anal sphincter at delivery. However, in patients remote from delivery with a sphincter defect and FI, the overlapping technique is preferred by most colorectal surgeons and urogynecologists.

With the overlapping method performed remote from delivery, short-term continence improvements of up to 85 percent were previously reported (Fleshman, 1991; Sitzler, 1996). However, recent reports show significant deterioration of continence during long-term postoperative surveillance (Baxter, 2003; Bravo, 2004; Halverson, 2002; Malouf, 2000). The reason for this deterioration following initial improvement remains unknown. Hypotheses include aging, scarring, and progressive pudendal neuropathy related either to the initial injury or to the repair. Patients who fail to improve after anal sphincteroplasty and who are found to have a persistent sphincter defect may be candidates for a second sphincteroplasty. However, those with an intact sphincter following repair and persistent symptoms are only considered candidates for conservative management or one of the salvage or minimally invasive surgical procedures described later.

Currently, there is no conclusive evidence that the overlapping method, if used at delivery, leads to superior results than the traditional end-to-end method of anal sphincter repair (Fitzpatrick, 2000; Garcia, 2005). Moreover, overlapping repair requires increased technical skills and carries the potential for increased blood loss, operating time, and pudendal neuropathy. For these reasons, the end-to-end technique is likely to remain the standard method for sphincter re-approximation at delivery until further data from randomized controlled trials are available. Importantly, given the strong association between anal sphincter lacerations and development of AI, emphasis should continue to focus on primary prevention of these lacerations.

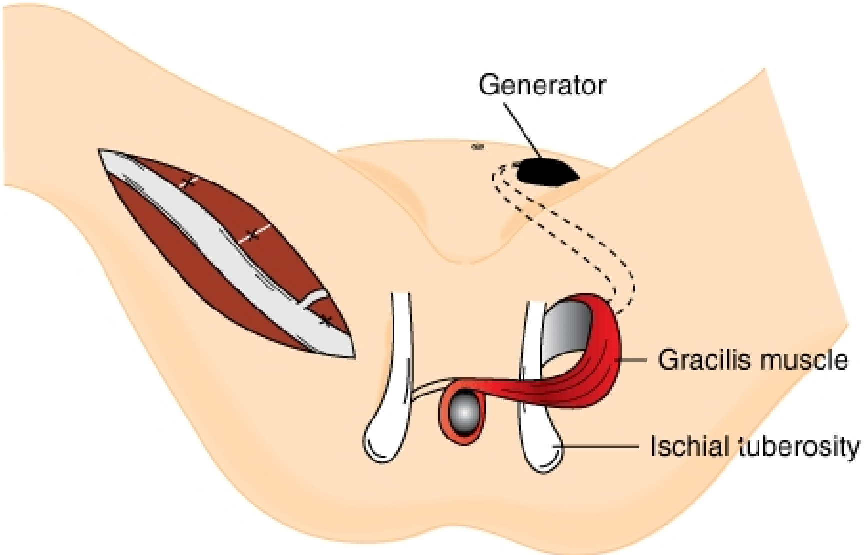
Postanal Pelvic Floor Repair

This repair is advocated for patients who have significant FI with no evidence of sphincter defects or neuropathy and who fail to improve with conservative management. The procedure is designed to re-establish the anorectal angle and to lengthen and tighten the anal canal. Through an intersphincteric approach, sutures are placed between the ends of the iliococcygeus, pubococcygeus, puborectalis, and external anal sphincter muscles. Although Parks originally reported incontinence improvement in up to 80 percent of patients, similar results have not been replicated (Parks, 1975; Browning, 1983).

Gracilis Muscle Transposition

This procedure is advocated for patients who have failed sphincter repair or those with a sphincter defect too large to allow muscle re-approximation (Baeten, 1991). *Dynamic graciloplasty* involves separating the gracilis tendon from its point of insertion at the knee, wrapping the muscle around the anus, and attaching the tendon to the contralateral ischial tuberosity (Fig. 25-8). The muscle is then stimulated with an electrical pulse generator that is implanted in the abdomen.

FIGURE 25-8



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dynamic graciloplasty. Note the gracilis muscles wrapped around the anus and attached to contralateral ischial tuberosity.

This procedure has a significant performance learning curve and is offered in only a few medical centers that have adequate patient volume and surgical experience. Complication rates of greater than 50 percent have been reported and overall success rates range below 35 percent (Chapman, 2002; Matzel, 2001; Thornton, 2004; Wexner, 2002). However, it is an acceptable option for many patients whose only alternative is a permanent stoma. This procedure is not currently performed in the United States, as the generator used to stimulate the gracilis muscle is not available.

Artificial Anal Sphincters

This procedure was first reported by Christiansen and Lorentzen in 1987 and is still considered experimental by many. It is indicated for patients with severe incontinence who have failed other treatment methods (Fig. 25-9). An inflatable cuff that mimics the function of the anal sphincter is implanted around the anus; a pressure-regulating balloon is implanted within the abdominal wall or iliac fossa; and a control pump is placed in the scrotum or the labia. When fully inflated, the cuff occludes the anal canal. This procedure carries a high rate of complications and subsequent implant removal. Similarly to the muscle transposition procedures, it has a considerable learning curve for most surgeons (Devesa, 2002; Parker, 2003).

FIGURE 25-9

Artificial anal sphincter.

Diversion (Colostomy or Ileostomy)

Diversion is reserved for patients with incapacitating FI who have failed other treatments (see Sections 43-15, Colostomy and 43-17, Ileostomy). For these selected patients, such procedures can significantly improve their quality of life.

MINIMALLY INVASIVE PROCEDURES FOR FECAL INCONTINENCE

Secca Procedure

This outpatient procedure is currently used in the United States to treat FI in patients with no evidence of sphincter defects or pudendal neuropathy. It involves delivery of temperature-controlled radiofrequency energy to the anal sphincter muscles by means of a specifically designed anoscope. Resulting tissue heating is believed to cause heat-induced collagen contraction followed by focal wound healing, remodeling, and tightening. In a multicenter study, Efron and colleagues (2003) showed a median 70 percent resolution of symptoms in 50 patients.

Sacral Nerve Stimulation

Sacral neuromodulation is presently used in the United States to treat selected cases of urge incontinence, urgency-frequency syndrome, and idiopathic nonobstructive urinary retention (see Section 42-12, Sacral Neuromodulation). This procedure is also currently under investigation for the treatment of FI (Ganio, 2001; Matzel, 1995, 2004). Although the mechanism of action remains unclear, some preliminary studies have shown a nearly 80-percent success rate for FI. As a result, there is tremendous enthusiasm and anticipation of further study results.

FUNCTIONAL ANORECTAL DISORDERS

In the current classification of functional gastrointestinal disorders, three functional anorectal disorders are recognized: (1) functional fecal incontinence (FI), (2) functional anorectal pain, and (3) functional defecation disorders (Table 25-6) (Drossman, 2006). Criteria for these and other functional GI disorders have been defined by the Rome III Foundation expert consensus organization. As shown in Table 25-6, these are primarily diagnosed based on patients' reported symptoms. As with other functional disorders, organic disease should be excluded prior to assignment of these diagnoses.

Table 25-6 Rome III Criteria of Functional Gastrointestinal Disorders
FUNCTIONAL ANORECTAL DISORDERS
Functional fecal incontinence
Functional anorectal pain
Chronic proctalgia
Levator ani syndrome
Unspecified functional anorectal pain
Proctalgia fugax
Functional defecation disorders
Dyssynergic defecation
Inadequate defecatory propulsion

Adapted from Drossman, 2006, with permission.

Functional Fecal Incontinence

Functional FI is defined by Rome III criteria as recurrent uncontrolled passage of fecal material for more than 3 months in an individual with anatomically normal defecatory muscles that function abnormally. As a result, fecal retention or diarrhea is common, and psychological disorders may be associated. The etiology is varied and causes may include disturbed intestinal motility, poor rectal compliance, impaired rectal sensation, and weakened pelvic floor muscles (Whitehead, 2001). Once diagnosed, functional FI is primarily treated with medical management or biofeedback, as described earlier.

Functional Anorectal Pain

Categories within this group are differentiated from one another by the duration of pain and by the presence or lack of associated puborectalis muscle tenderness. *Levator ani syndrome,* also known as *levator ani spasm,* usually presents as a pressure sensation or ache in the upper rectum. Rome III criteria require that symptoms are present for more than 3 months; episodes should last at least 20 minutes; and symptoms are associated with puborectalis muscle tenderness when palpated. In contrast, *proctalgia fugax* presents as sudden, severe anal or lower rectal pain that lasts for a few seconds to a few minutes. Pain may disrupt normal activities but episodes occur rarely more than 5 five times a year.

Treatments for levator ani syndrome are varied and may include, among others, trigger point release maneuvers, biofeedback, local heat, and pharmacologic agents such as nonsteroidal anti-inflammatory drugs, other analgesics, muscle relaxants, and tranquilizers (see Chap. 11, Treatment). In contrast, proctalgia fugax is typically managed with reassurance.

Functional Defecation Disorders

This group of disorders includes: (1) dyssynergic defecation and (2) inadequate defecatory propulsion disorders. *Dyssynergic defecation* is also called pelvic floor dyssynergia, anismus, outlet obstruction constipation, or spastic pelvic floor syndrome. It is

characterized by failed relaxation of the puborectalis muscle and EAS, which is needed for normal defecation. This condition is common and is thought to account for 25 to 50 percent of chronic constipation cases (Wald, 1990). Symptoms include chronic straining and impaired or incomplete evacuation. Diagnosis requires confirmation by EMG, manometry, or radiologic testing of persistent contraction of these muscles during attempted defecation. Other causes of constipation should also be excluded. Biofeedback interventions for dyssynergic defecation teach patients to relax their pelvic floor muscles while simultaneously applying downward intra-abdominal pressure (Valsalva maneuver).

RECTOVAGINAL FISTULA

Definition and Classification

Rectovaginal fistulas (RVFs) are congenital or acquired epithelial-lined tracts between the vagina and rectum. They are classified according to their location, size, and etiology. All of these features aid in selecting the appropriate management and in predicting outcome of surgical repair. The underlying cause of a fistula is believed to be the most important predictor of a successful outcome, as it takes into account tissue and overall patient health.

Most RVFs are related to obstetric events and occur in the distal third of the vagina just above the hymen (Fig. 25-10 and Table 25-7) (Greenwald, 1978; Lowry, 1988; Tsang, 1998). Defects can range from less than 1 mm to several centimeters in diameter, and most communicate with the rectum at or above the dentate line. In contrast, fistulas with an opening below the dentate line are also appropriately called *anovaginal fistulas.* Surgical management of these "low" RVFs depends on the condition of the EAS, but it is usually achieved by a perineal (transvaginal or transanal) approach. Midlevel RVFs are found in the middle third of the vagina, whereas high rectovaginal fistulas have their vaginal communication close to the cervix or the vaginal cuff. In cases with high RVFs, fistulas may open into the sigmoid colon. These fistulas may not be readily seen on examination and often require contrast or endoscopic studies for diagnosis and an abdominal approach for repair.

FIGURE 25-10

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Rectovaginal fistula in distal wall of posterior vagina in a woman who sustained a fourth-degree perineal laceration.

Table 25-7 Rectovaginal Fistula Risk Factors
Obstetric complications
Third- or fourth-degree laceration repair dehiscence
Unrecognized vaginal laceration during operative vaginal or precipitous delivery
Inflammatory bowel disease
Most commonly Crohn disease
Ulcerative colitis less common, as it is not a transmural disease
Infection
Most commonly cryptoglandular abscess located in the anterior aspect of the anal canal
Lymphogranuloma venereum
Tuberculosis
Bartholin abscess
Human immunodeficiency virus infection
Diverticular disease
Previous surgery in the anorectal area
Hemorrhoidectomy
Low anterior resection
Excision of rectal tumors
Hysterectomy
Posterior vaginal wall repairs
Pelvic radiation therapy
Neoplasm
Invasive cervical or vaginal cancer
Anal or rectal cancer
Trauma
Intraoperative
Coital

Diagnosis

PATIENT HISTORY

Patients with RVF usually complain of flatus or stool leakage per vagina. They may also present with recurrent bladder or vaginal infection, rectal or vaginal bleeding, and pain. Presenting symptoms are often suggestive of the underlying etiology. For example, patients with obstetric injury and large defects of the anterior portion of the anal sphincters may present with gross fecal incontinence. In contrast, those with an infectious or inflammatory process may complain of diarrhea, abdominal cramping, and fevers.

PHYSICAL EXAMINATION

Most low RVFs can be visualized during inspection of the perineum and distal portion of the posterior vaginal wall. Rectovaginal examination allows assessment of the thickness of the perineal body and anovaginal wall and may allow palpation and visualization of the actual defect. Some RVFs that are not readily seen on initial examination can be identified by noting air bubbles at the fistula's vaginal opening after filling the vagina with water. Alternatively, methylene blue can be instilled in the rectum after a tampon is placed in the vagina. The fistula and a gross assessment of its location can be identified by inspecting the level of blue staining on the tampon following its removal.

DIAGNOSTIC TESTING

If the fistula site is not determined by the above maneuvers, a contrast study is indicated. These include barium enema and computed-tomography (CT) scanning. Alternatively, vaginoscopy may be performed. The vaginal is filled with sterile water or saline, the labia are closed, and a small endoscope is inserted vaginally to inspect the walls.

Unless RVFs are obviously due to a prior obstetric event, a biopsy of the fistulous tract is indicated to investigate possible malignancy and inflammatory conditions. In addition, proctoscopy or colonoscopy is warranted if inflammatory bowel disease, malignancy, or infection is suspected or cannot be excluded.

Treatment

Treatment of RVF depends on the underlying etiology and the defect's size and location. Some women with small RVFs following obstetric trauma may be followed conservatively in anticipation of spontaneous healing of the fistulous tract (Goldaber, 1993; Rahman, 2003). Larger obstetric-related defects and other low fistulas are most often corrected surgically. Surgical techniques include: (1) a transvaginal or transanal approach through episioproctotomy (conversion of the defect into a complete perineal tear or fourth-degree laceration); (2) a fistulotomy with a tension-free layered closure without episioproctotomy; or (3) a fistulotomy with transvaginal purse-string method of repair without episioproctotomy as described in (Section 42-26, Rectovaginal Fistula Repair (Fig. 25-11). Additionally, endorectal flap advancement is used by colorectal surgeons, primarily for the treatment of complex perianal fistulas such as those with tracts of greater than 2.5 cm in size or those related to trauma or infection (MacRae, 1995). With flap advancement, the fistulous tract is excised, a broad-based flap of rectal wall is employed to obliterate the fistula's origin, and division of the sphincter muscles is avoided. Of these methods, better outcomes have been shown following RVF repair using anal sphincteroplasties compared with endorectal advancement flap (Tsang, 1998).

Large rectovaginal fistula in a woman who underwent midline episiotomy. Note the fistula is above an intact external anal sphincter muscle.

Surgical repair of a fistula should be delayed until surrounding tissues are free of edema, induration, and infection (Wiskind, 1992). In addition, preoperative endoanal ultrasonography of the EAS is important in these patients. For example, an episioproctotomy should be avoided if the sphincter is intact (Hull, 2007).

Midlevel vaginal fistulas are also often due to obstetric trauma and are repaired transvaginally or transanally by a tension-free layered closure or an endorectal advancement flap. High fistulas are most commonly repaired by a transabdominal approach using bowel resection of the involved segment followed by primary bowel re-anastomosis.

Success rates vary depending on the underlying cause and method of repair. Successful repairs following obstetrical injury vary from 78 percent to 100 percent (Khanduja, 1999; Tsang, 1998). Success rates of 40 to 50 percent have been recently been reported with rectal advancement flaps, and of 74 percent with episioproctotomy (Mizrahi, 2002; Sonoda, 2002). Fistulas due to other etiologies such as radiation, cancer, or active inflammatory bowel disease are more difficult to treat successfully. In general, success rates are highest with the first surgical attempt at repair (Lowry, 1988).

GENITOURINARY FISTULA

A genitourinary fistula is defined as an abnormal communication between the urinary (ureters, bladder, and urethra) and the genital (uterus, cervix, and vagina) systems. The true incidence of genitourinary fistula is unknown, although the generally accepted incidence approximates 1 percent or less of all genitourinary operations (Harris, 1995). This is most likely an underestimation because many are unreported or unrecognized. The most common type of genitourinary fistula is the vesicovaginal fistula and is discussed below (Goodwin, 1980).

Pathophysiology

Knowledge of the principles and phases of wound healing are important in understanding the pathogenesis of genitourinary fistula. After injury, tissue damage and necrosis stimulate inflammation, and the process of cell regeneration begins (Kumar, 2005). Initially at the injury site, new blood vessels form, termed *angiogenesis* . Three to five days after injury, fibroblasts proliferate and subsequently synthesize and deposit extracellular matrix, in particular collagen. This *fibrosis phase* determines the final strength of the healed wound. Collagen deposition peaks about seven days after injury and continues for a number of weeks. Subsequent maturation and organization of the scar, termed *remodeling* , augments wound strength. These phases are interdependent and are intrinsically involved in wound healing. Any disruption of this sequence eventually results in fistula formation. Most fistulas tend to present 1 to 3 weeks after tissue injury, a time during which tissues are most vulnerable to alterations in the healing environment, such as hypoxia, ischemia, malnutrition, radiation, and chemotherapy. Edges of the wound eventually epithelialize and a chronic fistulous tract is thus formed.

Classification

Although many classification systems exist for genitourinary fistula, there is no single accepted standardized scheme. Fistulas can develop at any point between the genital and urinary systems. Thus, one method of classification is based on anatomic communication (Table 26-1).

Table 26-1 Classification of Genitourinary Fistula Based on Anatomic Communication

	Urinary Tract		
	Ureter	**Bladder**	**Urethra**
Vagina	Ureterovaginal	Vesicovaginal	Urethrovaginal
	Vesicoureterovaginal		
Cervix	Ureterocervical	Vesicocervical	Urethrocervical
Uterus	Ureterouterine	Vesicouterine	Not reported

Vesicovaginal fistulas can also be characterized by their size and location in the vagina. They are termed *high vaginal* when found proximally in the vagina, *low vaginal* when noted distally, or *midvaginal* when identified centrally. For instance, post-hysterectomy vesicovaginal fistulas are often proximal or high in the vagina, and located at the level of the vaginal cuff.

Alternatively, some have classified vesicovaginal fistulas based on the complexity and extent of involvement (Elkins, 1999). In this scheme, complicated vesicovaginal fistulas are those that involve pelvic malignancy, prior radiation therapy, shortened vaginal length, or bladder trigone, or are distant from the vaginal cuff or greater than 3 cm in diameter.

In obstetric classification, high-risk vesicovaginal fistulas are described by their size (greater than 4 to 5 cm in diameter); involvement of urethra, ureter(*s*), or rectum; juxtacervical location with an inability to visualize the superior edge; and reformation following a failed repair (Elkins, 1999).

In addition, a surgical classification has been introduced as a method to objectively evaluate the repair of obstetric urinary fistulas (Waaldijk, 1995). In this system, type I fistulas are those that do not involve the urethral closure mechanism, type II fistulas do, and type III involve the ureter and include other exceptional fistulas. Type II fistulas are divided into: (A) without, or (B) with total or subtotal urethral involvement. Type IIB fistulas are further subdivided as to whether it is (a) without, or (b) with a circumferential defect.

Recently, a more comprehensive classification system has been proposed that integrates the fistula location in reference to a fixed point of anatomy, the size of the fistula, and the integrity of the surrounding tissues (Goh, 2004). In this scheme, genitourinary fistulas are initially divided into four types based on their distance from the external urethral meatus. They are further subdivided by the size of the fistula, the extent of scarring that surrounds the defect, and whether the vagina is reduced in length from scarring or from involvement of the fistula (Table 26-2).

Table 26-2 Classification of Genitourinary Fistula
This new classification divides genitourinary fistulae into four main types, depending on the distance of the fistula's distal edge from the external urinary meatus. These four types are further subclassified by the size of the fistula, extent of associated scarring, vaginal length, or special considerations.
Type 1: Distal edge of fistula >3.5 cm from external urinary meatus Type 2: Distal edge of fistula >2.5â€"3.5 cm from external urinary meatus Type 3: Distal edge of fistula 1.5â€">2.5 cm from external urinary meatus Type 4: Distal edge of fistula <1.5 cm from external urinary meatus
(a) Size <1.5 cm, in the largest diameter (b) Size 1.5â€"3 cm, in the largest diameter (c) Size >3 cm, in the largest diameter
i. None or only mild fibrosis (around fistula and/or vagina) and/or vaginal length >6 cm, normal capacity ii. Moderate or severe fibrosis (around fistula and/or vagina) and/or reduced vaginal length and/or capacity iii. Special consideration, e.g., postradiation, ureteric involvement, circumferential fistula, or previous repair.

From Goh, 2004, with permission.

Etiology

CONGENITAL

Congenital genitourinary fistulas are rare, with only ten cases reported in the literature (Asanuma, 2000). It is thought to result from either an abnormal fusion of the ureteric bud and the caudal end of the mÃ¼llerian duct with the urogenital sinus, or from incorporation of an aborted ureteric bud into a future wolffian duct remnant (see Chap. 18 and Fig. 18-1). These fistulas are

usually associated with other renal or urogenital abnormalities (Dolan, 2004).

ACQUIRED

Most vesicovaginal fistulas do not arise from developmental abnormalities but follow either obstetric trauma or pelvic surgery.

Obstetric Trauma

In developing countries, 90 percent of genitourinary fistulas arise from obstetric trauma, specifically from prolonged or obstructed labor (Arrowsmith, 1996). Their development in this setting reflects social customs and practices, lifestyle, or accepted obstetric management inherent to a particular society or geographic region (Meyer, 2007). For example, both childbearing at a young age, before the pelvis has developed or fully grown, and female circumcision, also termed *female genital mutilation* , may lead to a narrow vaginal introitus and can obstruct labor. Obstructed labor or malpresentation of the presenting fetal part can cause pressure or ischemic necrosis of the anterior vaginal wall and bladder, subsequently resulting in fistula formation. Alternatively, vaginal trauma may result from damage by instruments used to deliver stillborn infants or perform abortion. Malnutrition and limited health care in many of these countries further complicates wound healing. In contrast, in most developed countries, fistulas uncommonly follow obstetric procedures or deliveries. On rare occasion, cesarean deliveries, usually those accompanied by obstetric complications, have led to complex urinary fistulas (Billmeyer, 2001).

Pelvic Surgery

In developed countries, iatrogenic injury during pelvic surgery is responsible for 90 percent of vesicovaginal fistulas and the accepted incidence of fistula formation after pelvic surgery is 0.1 to 2 percent (Harris, 1995; Lee, 1988; Mattingly, 1978; Tancer, 1992). Eighty to 90 percent of genitourinary fistulas are related to surgery by obstetrician-gynecologists, whereas the remainder result from procedures performed by urologists and colorectal, vascular, and general surgeons. In industrialized countries, hysterectomy is the most common surgical cause of vesicovaginal fistula, accounting for approximately 75 percent of fistula cases (Symmonds, 1984). When all types of hysterectomy are included, vesicovaginal fistula is estimated to complicate 0.8 per 1,000 procedures (Harkki-Siren, 1998). Laparoscopic hysterectomies were associated with the greatest incidence (2 per 1,000), followed by abdominal (1 per 1,000), and vaginal (0.2 per 1,000) hysterectomies.

Because most genitourinary fistulas have an operative etiology, prevention and intraoperative recognition of lower urinary tract injury is imperative. Use of intraoperative cystoscopy has been shown to improve the detection rate of lower urinary tract injuries. Gilmour (1999) found in hysterectomies performed without cystoscopy, that ureteric and bladder injuries have crude occurrence rates of 1.6 and 2.6 per 1,000 procedures, respectively. With intraoperative cystoscopy, the detection rate of these injuries increased to 6.2 per 1,000 cases for ureteral injury and 10.4 per 1,000 cases for bladder injury. Thus, the implementation of routine cystoscopy may be a useful adjunct in the detection of lower urinary tract injury during hysterectomy. This in turn may ultimately result in a lower incidence of genitourinary fistula.

Other Causes

Although surgical and obstetric causes account for most urinary fistulas, other causes have been reported and include radiation therapy, malignancy, trauma, foreign bodies, infections, pelvic inflammation, and inflammatory bowel disease.

Radiation

Radiation therapy induces an endarteritis, which leads to tissue necrosis, and subsequent potential fistula formation. This modality is a frequent underlying cause and 6 percent of genitourinary fistulas are thought to result from radiation (Lee, 1988). Although most damage following radiation treatment develops within weeks and months, fistulas associated with radiation therapy may present up to 20 years after the original insult (Graham, 1967; Zoubek, 1989).

Malignancy

Tissue necrosis and deterioration is commonly associated with malignancy and may lead to urinary fistula formation. Emmert and Kohler (1996) found a 1.8-percent incidence of rectovaginal and vesicovaginal fistula in their analysis of nearly 2,100 women with cervical cancer. For this reason, tissue biopsy should routinely be performed in a woman with a fistula and history of malignancy.

Trauma and Foreign Body

Trauma sustained during sexual activity or sexual assault can result in genitourinary fistula formation and has been estimated to cause 4 percent of these defects (Kallol, 2002; Lee, 1988). Foreign bodies such as a neglected pessary, an aerosol cap, and vesical calculi are also documented agents (Binstock, 1990; Dalela, 2003; Grody, 1999).

Foreign bodies introduced during surgery such as collagen injected transurethrally and synthetic materials used in urethral sling procedures have also been reported (Kobashi, 1999; Pruthi, 2000). During sling surgeries, placement of the synthetic mesh under excess tension may contribute to increased tissue stress and necrosis. Accordingly, initial material selection and patient evaluation for risk factors of poor wound healing play important roles in fistula prevention (Giles, 2005). Materials that minimize the inflammatory foreign body reaction are preferred and will maximize biocompatibility. Ideally, a material should also be nontoxic, nonantigenic, and porous enough to admit immune and phagocytic cells and native tissue ingrowth (see Chap. 24, The Use of Mesh and Materials in Reconstructive Pelvic Surgery) (Birch, 2002).

Miscellaneous

Other rare causes of fistula formation include infections such as lymphogranuloma venereum, urinary tuberculosis, pelvic inflammation, and syphilis; inflammatory bowel disease; and autoimmune disease (Ba-Thike, 1992; Montiero, 1995). Moreover, conditions that interfere with healing, such as poorly controlled diabetes mellitus, smoking, local infection, peripheral vascular disease, chronic steroid use, and malignancy are risk factors.

Clinical Presentation

Vesicovaginal fistula classically presents with unexplained continuous urinary leakage from the vagina after a recent operation. Depending on the size and location of the fistula, the amount of urine will vary. Occasionally small-volume, intermittent leakage is mistaken for postoperative stress incontinence. For this reason, patients with new-onset urinary leakage should be examined thoroughly to exclude fistula formation. Other less specific symptoms of genitourinary fistula include fever, pain, ileus, and bladder irritability.

Vesicovaginal fistula may present days to weeks after the initial inciting surgery, and those following hysterectomy typically present at 1 to 3 weeks. Some fistulas, however, have longer latent periods and can cause symptoms a number of years later.

Diagnosis

HISTORY AND PHYSICAL EXAMINATION

A thorough history and physical examination identifies most cases of vesicovaginal fistula. Accordingly, historical information regarding obstetric deliveries, prior surgeries, previous management of fistula, and treatment of malignancy, especially involving pelvic surgery and radiation therapy, should be documented.

The physical examination is equally important, and often visual inspection during physical examination will identify the defect. A meticulous assessment for other fistulous tracts should be performed, and their location and size noted. Vaginoscopy has been described by some to improve fistula identification. For this evaluation, a laparoscope is inserted into a vagina, whose walls are held apart by a translucent plastic speculum (Andreoni, 2003).

During evaluation, it is mandatory to differentiate urinary leakage through a fistula (extraurethral leakage) from stress urinary incontinence (transurethral leakage). Moreover, occasionally the source of fluid present in the vagina is unclear and a small amount of urine can easily be mistaken for vaginal discharge. Measurement of the vaginal fluid's creatinine content, however, is an inexpensive test that may be used to confirm urine. Although levels of creatinine in urine can vary, with mean levels reaching 113.5 mg/dL, a value greater than 17 mg/dL is consistent with urine (Barr, 2005).

DYE INSTILLATION

Although the ideal method of confirming genitourinary fistula is by direct visualization, there are instances in which physical examination and inspection are unrevealing. In these circumstances, bladder instillation of visually distinct solutions such as methylene blue, sterile milk, or indigo carmine can often indicate the location.

When the presence of a urinary fistula is uncertain, or the location in the vagina cannot be identified, a modified *tampon test* or

three-swab test is recommended (Moir, 1973). During testing, gauze is packed sequentially into the vaginal canal. A diluted solution of methylene blue or indigo carmine is instilled into the bladder in a retrograde fashion using a catheter. After the patient has engaged in 15 to 30 minutes of routine activity, the gauze is removed serially from the vagina and inspected for presence of dye. The specific gauze colored with dye suggests where in the vagina a fistulous tract is locatedâ€"a proximal or high location in the vagina for the innermost gauze, and a low or distal fistula for the outermost. If the distally placed sponge is stained with dye, however, it is important to confirm that it was not contaminated by stress incontinence.

CYSTOURETHROSCOPY

This form of endoscopy is another valuable adjunct to diagnostic evaluation (Fig. 26-1). It allows localization of the fistula, determination of its proximity to the ureteral orifices, and assessment of surrounding bladder mucosa viability. In addition, Andreoni and co-workers (2003) described the use of cystourethroscopy and vaginoscopy concurrently to identify vesicovaginal fisula.

A. Cystoscopic view of vesicovaginal fistula **(arrow)** **B.** Probe placed through fistulous tract to facilitate cystoscopic visualization.

URETERAL INVOLVEMENT

Concomitant ureteral involvement is estimated to complicate 10 to 15 percent of vesicovaginal fistulas and should be excluded in the diagnostic evaluation (Goodwin, 1980). Accordingly, intravenous urography is used to assess integrity of the upper collecting system and ureteral involvement in the fistula. Retrograde pyelography generally has the same diagnostic value as intravenous urography. However, some authors have attested to its higher diagnostic accuracy in detecting ureterovaginal fistulas (Dmochowski, 2002).

Alternatively, phenazopyridine hydrochloride (Pyridium, Warner Chilcott, Rockaway, NJ) can be used in conjunction with the three-swab test to determine if there is ureteral involvement. This agent is administered orally, is excreted renally, acts as a topical bladder analgesic, and as a side effect stains the urine orange. Women with suspected ureteral involvement are instructed to take a 200-mg oral dose a few hours before their clinic appointment. Gauze is packed serially into the vagina as described previously. If the most proximal (innermost) sponge is colored with orange dye, ureteral involvement is suspected. If both orange and blue dyes are seen, then both the bladder and ureter(*s*) are typically involved.

VOIDING CYSTOURETHROGRAPHY

This radiologic study can also demonstrate leakage into the vagina and help confirm the presence, location, and number of fistulous tracts (Fig. 26-2). Another radiographic tool that has been used to identify genitourinary fistula is sonography with color Doppler flow (Volkmer, 2000). The efficacy of this technique has not been substantiated, and some have documented low sensitivity rates for fistula detection (Adetiloye, 2000).

Treatment

CONSERVATIVE TREATMENT

Occasionally, genitourinary fistulas may spontaneous close during continuous bladder drainage using an indwelling urinary catheter. Davits and Miranda (1991) described four cases of successful conservative management of vesicovaginal fistula with urinary catheter drainage ranging from 19 to 54 days. Additionally, Waaldjik (1994) found that 21 of 170 patients (12 percent) treated by catheterization alone had fistulas that healed spontaneously.

Data that correlate fistula size and success of conservative management, however, are limited. But generally, the larger the fistula, the less likely it is to heal without surgery. In 10 percent of cases, urinary fistulas close spontaneously after 2 to 8 weeks of transurethral catheterization, especially if the fistula is small (2 to 3 mm diameter) (Romics, 2002). In another series, small fistulas up to 2 cm in diameter spontaneously healed in 50 to 60 percent of patients treated with an indwelling catheter (Waaldijk, 1989). If the fistula has not closed within 4 weeks, however, it is unlikely to do so, probably secondary to collagen deposition and epithelialization of the fistulous tract (Bazi, 2007; Davits, 1991). Moreover, continued urinary drainage may lead to further inflammation and irritation of the bladder (Zimmern, 1991).

Fibrin sealant has been described for the treatment of vesicovaginal fistula. However, its use has been limited to an adjunctive capacity rather than primary surgical treatment (Evans, 2003). First, the data regarding the effectiveness of fibrin sealant are sparse, with a lack of well-designed trials. Secondly, compared with surgical treatment, fibrin sealant monotherapy has not been as durable and recurrence results (Kanaoka, 2001).

An attempt at conservative treatment is usually warranted. However, a balance between a conservative approach and a patient's desire for an expedited repair should be considered. The timing of intervention is dependent on achieving a compromise between reasonable conservative efforts and addressing the patient's immediate distress and quality of life. Indeed, most urinary fistulas ultimately require surgical intervention.

SURGICAL TREATMENT

General Principles

Although the first successful repair of a vesicovaginal fistula was reported hundreds of years ago, the fundamental principles of repair have withstood the test of time and result in a high cure rate with the first attempt at surgical repair. These fundamentals include appropriate pre- and intraoperative preparation; timely repair; multilayer, tension-free closure; assessment of adequate surrounding tissue viability; and postoperative bladder drainage.

Cure Rates

Surgical repair of genitourinary fistula is associated with high rates of cure (67 to 100 percent) (Dmochowski, 2002). Factors that affect this success rate include viability of the surrounding tissue, duration of the fistulous tract, prior irradiation, surgical technique, and surgeon experience. The first attempt at surgical repair is usually associated with the best chance of successful healing (Weed, 1978). Surgical repair of obstetric fistula has higher success rates, and 81 percent are corrected with the first attempt, and 65 percent with the second (Elkins, 1994; Hilton, 1998).

Timing of Repair

Traditional teaching recommends delayed repair of fistulas at 3 to 6 months after injury. However, this old dictum is probably no longer applicable. Most agree that unless there is severe infection or acute signs of inflammation, waiting is not necessary (Wein, 1980). Early surgical intervention of uncomplicated fistulas does not affect closure rates, yet appears to reduce social and psychological patient distress (Blaivas, 1995). Fistulas identified within the first 24 to 48 hours postoperatively can be safely repaired immediately with success rates of 90 to 100 percent (Blandy, 1991; Persky, 1979; Wang, 1990). Intervention should be individualized, balancing patient quality of life with viability of surrounding tissue.

Route of Surgical Repair

Although there are many different types of surgical repair for vesicovaginal fistula, data that support an optimal route are limited, and the lack of consensus may reflect the disparity in surgeon expertise and experience. Among important surgical considerations, ability to gain access to the fistula is essential and commonly dictates surgery selection. Fortunately, success rates are high whether the route of repair is transvaginal or transabdominal.

Vaginal

The transvaginal approach to genitourinary fistula repair is straightforward and direct. Compared with abdominal approaches, it is associated with shorter operative times, decreased blood loss, less morbidity, and shorter hospital stays (Wang, 1990). The transvaginal route also allows the use of ancillary equipment, such as ureteral stents. This is particularly useful if the fistula is located near ureteral orifices.

Latzko Technique

The *Latzko technique* has been likened to a partial colpocleisis (see Section 42-10, Vesicovaginal Fistula: Latzko Technique). Typically, it surgically apposes the most proximal portions of the anterior and posterior vaginal walls and thus partially obliterates the uppermost vagina. Since vaginal depth is potentially compromised, this technique is not an appropriate option if preservation of vaginal depth and retention of sexual function are desired.

Classical Technique

In contrast to the Latzko method, the *classical technique* involves excision of the fistulous tract. After excision of the fistula, the vaginal epithelium is undermined and widely mobilized. The bladder mucosa is closed, followed by subsequent closure of two layers of fibromuscular tissue. A watertight repair is confirmed and the vaginal epithelium is reapproximated.

Abdominal (Transperitoneal)

Difficult fistulas or those requiring supravesical urinary diversion require an abdominal approach (see Section 42-10, Vesicovaginal Fistula: Latzko Technique). The fistula is accessed through an intentional cystotomy. Similar to the transvaginal approach, the bladder and vaginal epithelia at the fistula site are undermined for approximately 1.5 cm in all directions. After adequate mobilization, the fistula site is closed in layers. This approach is used in situations in which: (1) the fistula is located proximally in a narrow vagina; (2) it is in close proximity to the ureteral orifices; (3) a concomitant ureteric fistula is present; (4) previous repairs of the fistula have been unsuccessful and the fistula is recurrent; (5) the vaginal walls are rigid with little mobility; (6) the fistula is large or complex in configuration; or (7) there is a need for an abdominal interposition graft.

Laparoscopic

Evidence-based support for laparoscopic genitourinary fistula repair has been limited to case reports and expert opinion (Das Mahapatra, 2007; Nezhat, 1994; Ou, 2004). The technique was first described in 1994 by Nezhat and requires advanced laparoscopic surgical skills. As a result, success with this approach appears to be highly dependent on surgeon expertise and experience.

Interpositional Flaps

Viability of the surrounding tissue is an important consideration in the repair of genitourinary fistula. When intervening tissues for fistula closure are weak and poorly vascularized, various tissue flaps may be placed vaginally or abdominally between the bladder and the vagina to lend support and blood supply (Eisen, 1974; Martius, 1928, Obrink, 1978; Patil, 1980; Sharma, 1980). Interposition flaps are useful in situations in which tissue viability is in question. However, their utility in uncomplicated cases of vesicovaginal fistula is unclear.

Urethrovaginal and Other Genitourinary Fistulas

Although vesicovaginal fistulas are the most common type of genitourinary fistula, other fistulas can exist and may be described based on their communication between anatomic structures. Urethrovaginal fistulas commonly result from surgery involving the anterior vaginal wall, in particular, anterior colporrhaphy and urethral diverticulectomy (Blaivas, 1989; Ganabathi, 1994a). As with vesicovaginal fistula, obstetric trauma remains the most common cause of urethrovaginal fistulas in developing countries. Here, prolonged labor with ensuing tissue necrosis results in development of fistulas. Frequently, patients present with continuous urinary drainage into the vagina or with stress urinary incontinence. The principles of repair are similar: layered closure, tension-free repair, and postoperative bladder drainage. Other types of genitourinary fistula can also occur (see Table 26-1).

URETHRAL DIVERTICULUM

A urethral diverticulum is a cystic enlargement of a paraurethral gland, which is found in the anterior vaginal wall and communicates directly with the urethra (Fig. 26-3). Often fluid filled, this outpouching of the urethra is commonly asymptomatic and frequently diagnosed incidentally on routine examination. However, many present with symptoms and often require surgical excision.

FIGURE 26-3

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Transurethral expression of discharge with compression of urethral diverticulum seen in anterior vaginal wall.

Incidence

Urethral diverticulum is reported to develop in 1 to 5 percent of the general female population and because of greater awareness and radiologic advances, rates of diagnosis are increasing (Dmochowski, 2002). This incidence may be an underestimation of the true incidence because diverticula are frequently asymptomatic, and thus underreported. However, in women with lower urinary tract symptoms, the incidence dramatically increases and may reach 40 percent (Stewart, 1981).

Urethral diverticulum may be found in any age group, but is diagnosed most often in the third to sixth decades of life and more commonly in females than in males (Aldridge, 1978). Although some authors have reported a 6:1 predominance of urethral diverticula in African-Americans compared with Caucasians, others have found no racial predisposition for the condition (Davis, 1970; Leach, 1987).

Etiology and Pathophysiology

CONGENITAL DIVERTICULUM

The etiology of urethral diverticula is unclear. Although most are thought to be acquired, diverticula of congenital origin have been reported (Bhatnagar, 1999; Nel, 1955). Congenital causes of urethral diverticula include persistence of embryologic remnants, defective closure of the ventral portion of the urethra, and congenital cystic dilatation of paraurethral glands (Ratner, 1949).

An appreciation of the embryology and anatomy of the female genital tract and surrounding structures contributes, in part, to our

understanding of congenital urethral diverticulum. During development of the vagina, the caudal aspect of the paired mÃ¼llerian tubes fuses with an evagination of the urogenital sinus. The mÃ¼llerian tubes form the upper vagina, whereas the urogenital sinus gives rise to the distal vagina and vestibule (see Fig. 18-4). In the vagina, mÃ¼llerian mucinous columnar epithelium is replaced by squamous epithelium of the urogenital sinus. Similarly, the epithelium of the female urethra is also derived from the urogenital sinus. When the process of epithelial replacement is arrested, small foci of mÃ¼llerian epithelium may persist and may form cysts or diverticula.

ACQUIRED DIVERTICULUM

More commonly, diverticula are acquired and may result from infection, birth trauma, and traumatic instrumentation.

The most widely held theory regarding urethral diverticular development dates back to Routh (1890) and involves the paraurethral glands and their ducts. The paraurethral glands surround and cluster most densely along the urethra's inferolateral border (Fig. 26-4). Of these glands, the Skene glands are the most distal and typically the largest. The paraurethral glands connect to the urethral canal via a network of branching ducts. The arborizing pattern in portions of this network helps to explain the complexity of some urethral diverticula (Vakili, 2003).

FIGURE 26-4

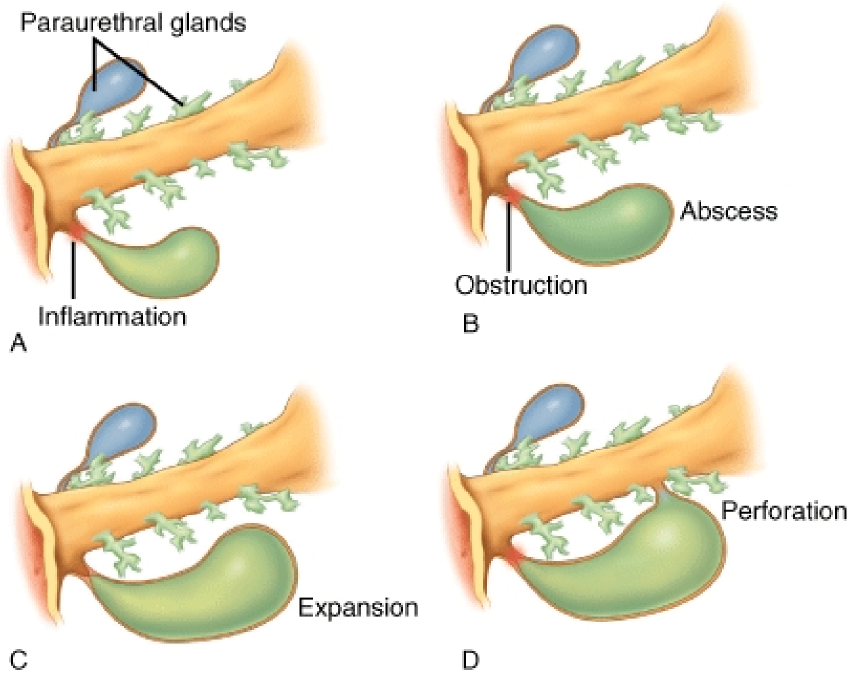
Complex configuration of paraurethral glands. (*From Huffman, 1948, with permission* .)

Routh theorized that infection and inflammation obstructs these ducts, leading to cystic dilation. If intervention is not instituted promptly, abscess formation may ensue. Subsequent abscess progression and continued inflammation can lead to submural rupture of the gland into the urethral lumen, creating a communication between the two (Fig. 26-5). As the infection clears, the dilated diverticular sac and communicating ostium into the urethra persist. Of infectious agents, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are organisms commonly associated with urethritis and severe inflammation of the paraurethral glands.

FIGURE 26-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Mechanism of urethral diverticulum development. (*From Elkins, 1999, with permission* .)

In addition to infection, damage to urethral tissue may lead to tissue swelling and paraurethral duct obstruction. Accordingly, urethral trauma sustained during childbirth and during urethral instrumentation has been suggested as an etiology (McNally, 1935). Moreover, different social customs and obstetric practices in the developing world can potentially contribute to urethra trauma and diverticulum development. Obstetric trauma may result from delivery at an early age, prolonged labor, and vaginal trauma during delivery. However, Pathak and House (1970) found that 40 percent of urethral diverticula in their series developed in nulliparous women, suggesting that causes in addition to childbirth are associated. For example, female genital mutilation or repeated urethral dilatations may result in urethral trauma.

Calculi

Stones may develop within large diverticulum, and the reported frequency approximates 10 percent (Perlmutter, 1993). Stones may be singular or multiple and are usually composed of calcium oxalate or calcium phosphate. Stagnation of urine and precipitation of salts within the diverticular sac lead to crystal and subsequent stone formation.

Cancer

Malignant transformation within a urethral diverticulum is rare and accounts for only 5 percent of urethral cancer. Although most of these tumors are adenocarcinomas, transitional cell and squamous cell carcinomas have also been identified (Clayton, 1992; Young, 2007). These tumors typically are found in women in their 60s or 70s. Although hematuria and irritative voiding complaints are common, palpation of a periurethral mass and urinary obstructive symptoms should prompt biopsy (Ghoniem, 2004). Because fewer than 100 cases of urethral cancer associated with urethral diverticula have been reported, development of definitive treatment strategies has been limited. Currently, these cancers are treated by anterior exenteration or by diverticulectomy, alone or with adjuvant radiation therapy (Shalev, 2002).

Classification

Early classification systems organized urethral diverticula according to their radiographic complexity and described them as: (1) simple saccular, (2) multiple, or (3) compound or complex with branching sinuses (Lang, 1959). Alternatively, to standardize surgical treatment, Ginsburg and Genadry (1983) created a preoperative classification system based on urethral location. This system organizes diverticula depending on their urethral location and describes lesions as type 1 (proximal third), type 2 (middle third), and type 3 (distal third).

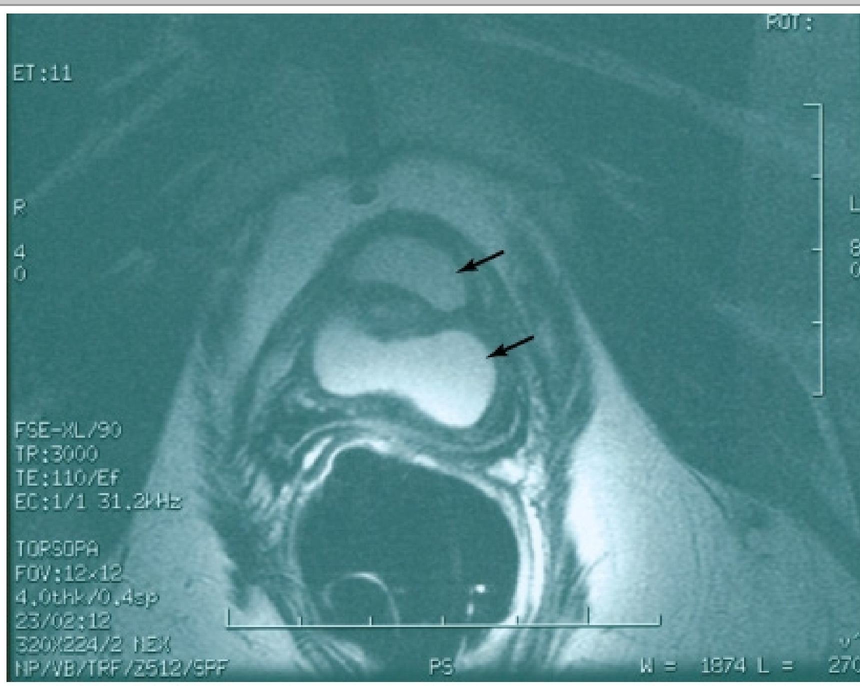
In an attempt to fully incorporate all characteristics necessary to adequately assign treatment, Leach and co-workers (1993) constructed the L/N/S/C3 classification system. In this system, the characteristics of a diverticulum are described according to its location (L), number (N), size (S), and communication, configuration, and continence status of the patient (C3).

Assigning location to these lesions is important in determining if certain surgical techniques, such as marsupialization, are feasible. Location is described in relation to the urethra and is defined as distal, mid-, or proximal urethral, and as with or without extension beneath the bladder neck. In their series of 61 patients, these investigators found that most were in the midurethra (62 percent). Logically, this distribution reflects the predominance of paraurethral glands along the middle third of the urethra.

In addition to location, the number of diverticula is an important determination preoperatively. Inadequate excision and symptom persistence may follow a failure to identify multiple diverticula. Diverticulum size is measured in centimeters and similarly may influence treatment options. For example, some authors recommend concomitant interpositional tissue flaps for large diverticula (Dmochowski, 2002). Moreover, urinary incontinence may develop de novo or persist if the diverticulum is extremely large and involves sphincter continence mechanisms.

The configuration of the diverticula may be described as solitary or multiloculated and as simple, saddle-shaped, or circumferential (Fig. 26-6). Preoperative knowledge regarding configuration can aid in complete surgical excision and allows for interpositional flap preparation for those cases requiring extensive urethral resection (Rovner, 2003).

FIGURE 26-6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Magnetic resonance image of a circumferential urethral diverticulum. **Arrows** show diverticulum extending around the urethra.

Obviously, successful repair of the urethral wall defect depends in great part on identifying the opening of the diverticulum into the

urethral canal. Preoperative determination of the communication site is thus important, with ostia being classified as proximal, mid-, or distal urethral. Leach and his associates found mid-urethral communication sites to be the most common (60 percent), followed by proximal (25 percent) and distal (15 percent) urethral sites.

Finally, in this classification system, the continence status and urethral hypermobility of the patient is documented. Almost half of the patients in their series had stress urinary incontinence, and these authors suggest that the presence of urethral hypermobility is an indication for concomitant anti-incontinence surgery. Although several studies have documented the safety of performing concurrent bladder-neck suspension, this approach is still considered by some as controversial due to concerns of urethral erosion following suspension (Bass, 1991; Faerber, 1998; Ganabathi, 1994b).

Although there is no universal consensus on this issue, it seems reasonable to treat the diverticulum first and then to consider anti-incontinence surgery if urinary incontinence persists. Pursuing treatment in this staged fashion is a particularly realistic option because of the current armamentarium of minimally invasive surgical procedures for the treatment of urinary incontinence, such as midurethral slings.

Patient Signs and Symptoms

Urethral diverticula are frequently asymptomatic and discovered incidentally on gynecologic or urologic examination for other complaints. However, when symptomatic, their presentations may vary and reflect their characteristics, especially size, location, and extension. Postvoid dribbling and egress of discharge through the urethra with compression of a suburethral mass are pathognomonic. However, few women present so classically. For most patients, symptoms are nonspecific and include pain, dyspareunia, and a number of urinary symptoms. In a retrospective review, Romanzi and colleagues (2000) found that pain was one of the most common symptoms reported (48 percent). Pain is thought to result from occlusion of the diverticular neck and cystic dilatation behind the obstruction. In addition, dyspareunia may develop if the diverticulum is sufficiently large, inflamed, or infected. Accordingly, women may note either entry or deep dyspareunia, depending on whether the diverticulum is distal or proximal.

A large diverticulum can often be mistaken for early-stage pelvic organ prolapse, especially when the presenting complaint is vaginal fullness, bulge, or pressure. In these cases, the palpable vaginal mass caused by a diverticulum may be mistaken for a cystocele or rectocele. Careful systematic palpation of the vaginal wall will distinguish prolapse from a discrete vaginal wall cyst or diverticulum in most cases.

A variety of lower urinary tract symptoms are commonly associated with urethral diverticulum. Specifically, urinary incontinence is noted by 35 to 60 percent of affected women. This typically results from involvement of the diverticulum with the continence mechanism or with support of the urethrovesical junction (see Chap. 23, Continence) (Romanzi, 2000; Ganabathi, 1994b). In addition, during micturition, urine may enter the diverticular sac, only to later spill from the sac and present as postvoid dribble or as urinary incontinence. Urinary retention has also been reported to complicate diverticula (Nitti, 1999). Because symptoms of retention frequently accompany cancers growing within a diverticulum or around the urethra, women with urinary retention and an associated periurethral or urethral induration require biopsy to exclude malignancy (von Pechmann, 2003).

Infection commonly complicates urethral diverticulum. In their treatment of 18 women with diverticula, Fortunato and associates (2001) noted acute cystitis in eight, dysuria in seven, and recurrent cystitis in 11.

Diagnosis

For many women, urethral diverticula may be diagnosed using simply a detailed history, physical examination, and high index of suspicion. Patient history should focus on the common characteristics and symptoms of diverticula noted earlier. In addition, a history of prior vaginal trauma, infections, or surgery should be sought. However, despite available clinical and radiologic tools, the diagnosis for many women is delayed, as women may be treated for stress or urge incontinence, chronic cystitis, trigonitis, urethral syndrome, vulvovestibulitis, cystocele, and idiopathic chronic pelvic pain prior to identification of a diverticulum (Romanzi, 2000). Moreover, the diverticulum itself may mimic a Gartner duct cyst, vaginal inclusion cyst, ectopic ureterocele, or endometrioma (Chowdhry, 2004).

PHYSICAL EXAMINATION

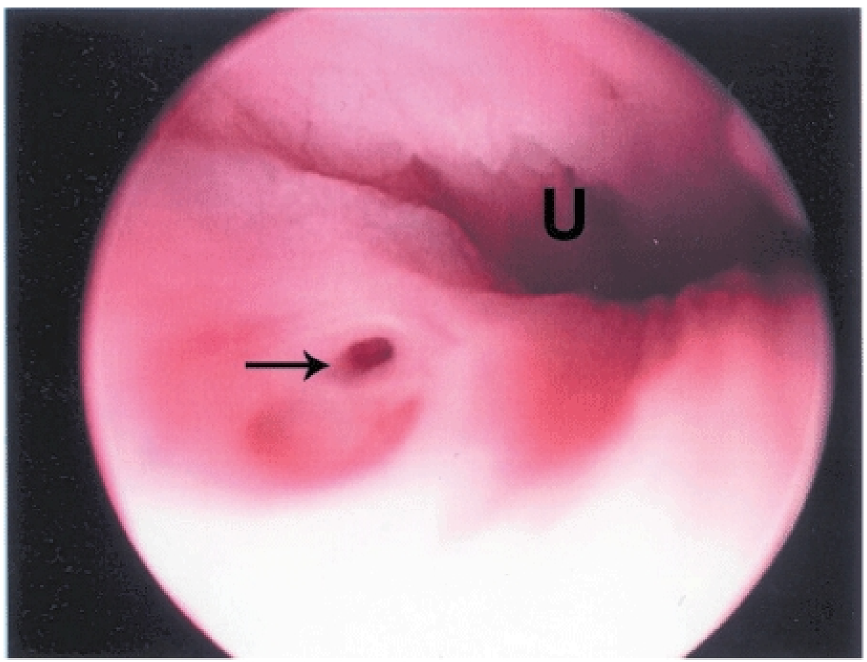
On examination, the most common finding is an anterior vaginal mass underlying the urethra and is detected in 50 to 90 percent of symptomatic patients. (Ganabathi, 1994b; Gerrard, 2003; Romanzi, 2000). Although urethral expression of purulent material with compression of the mass is common, failure to demonstrate transurethral expression of discharge does not exclude the diagnosis. Stenosis of the diverticular duct may obstruct sac emptying in these cases. Meticulous examination and palpation should be performed along the entire course of the urethra. Once diverticula are identified, their size, borders, consistency, and number should be determined.

However, when physical examination alone precludes complete delineation of these characteristics, further diagnostic testing may be required. The diagnosis of urethral diverticulum has increased in the past few decades due to improved diagnostic modalities. Of available tests, each has significant advantages and disadvantages. For this reason, investigators may disagree as to which should be chosen primarily in evaluation of urethral diverticula. Accordingly, clinicians should be familiar with the each modality's strengths and select whichever best fits the clinical setting.

CYSTOURETHROSCOPY

Of the diagnostic procedures used to detect urethral diverticula, cystourethroscopy is the only modality that allows direct inspection of the urethra and bladder. During cystourethroscopy, fingers pressed upward against the anterior vaginal wall occlude the bladder neck and allow the distending medium to create positive pressure and open diverticular ostia (Fig. 26-7). Use of a zero-degree cystoscopic lens allows complete assessment of the urethra, aiding direct visualization of diverticular ostia and a display of purulent discharge from them.

FIGURE 26-7



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Diverticular opening visualized on cystourethroscopic examination (arrow). U = urethra.

A primary advantage to cystourethroscopy includes its accuracy in diverticula detection (Summitt, 1992). In addition, many women with diverticula present with nonspecific lower urinary tract symptoms and endoscopic evaluation of the urethra and bladder allow exclusion of other etiologies for these symptoms such as urethritis, cystitis, stones, or stenosis. Despite these advantages and its common use by urogynecologists, cystourethroscopy is used less frequently by gynecologic generalists, because of the cystoscopic expertise and general knowledge of bladder and urethral mucosal anatomy it requires. Even for clinicians who are experienced with

cystourethroscopy, this tool may still fail to display all diverticula. For example, a poor seal between the cystoscope and distal urethral muscosa may lead to inadequate distension and failure to identify distally located diverticula. Moreover, those whose ostia are stenotic, and thus do not communicate with the urethral lumen, may be missed. Cystourethroscopy is minimally invasive, and patient pain and risk of postprocedural infection are also legitimate concerns. Lastly, important information regarding size, consistency, and circumferential extent of the diverticulum may not be obtained with this tool.

VOIDING CYSTOURETHROGRAM

Voiding cystourethrogram (VCUG) is used by many as an initial tool in the evaluation of urethral diverticulum. Radiographic contrast instilled into the bladder will fill the diverticular sac during voiding and postvoid radiographs display the diverticulum.

Although this test is painless and simple to perform, its overall reported accuracy approximates only 65 percent, and thus many prefer positive-pressure urethrography as a primary diagnostic tool (O'Shaughnessy, 2006). Additionally, VCUG involves exposing the patient to ionizing radiation, albeit minimal.

POSITIVE-PRESSURE URETHROGRAPHY

Following its introduction by Davis and Cian (1956), positive-pressure urethrography (PPUG) dramatically improved the detection of urethral diverticula, and at that time rapidly became the standard of care. During PPUG, a double-balloon, triple-lumen catheter is inserted through the urethra, and its tip enters the bladder (Fig. 26-8) (Trattner catheter, CR Bard, Inc., Murray Hill, NJ). Inflating the proximal balloon allows it to be pulled snug against and occlude the urethra at the urethrovesical junction. The distal balloon obstructs the distal urethra. A single catheter port between the two balloons allows instillation of radiopaque contrast dye, subsequent distension of the urethra, and expansion of the diverticulum under positive pressure.

FIGURE 26-8

Trattner double-balloon catheter used to diagnose urethral diverticula. (*From Greenberg, 1981, with permission.*)

Urethrography is an effective modality for accurately identifying diverticula, and its sensitivity surpasses that of VCUG (Jacoby, 1999; Wang, 2000). Golomb and colleagues (2003) in their small series found a 100-percent sensitivity with PPUG compared with 66 percent for VCUG. In every case in their study, PPUG defined the location, size, configuration, and communication of the diverticula to the urethra. However, PPUG can be time-consuming, technically difficult, and associated with patient discomfort and risk of postprocedural infection. Moreover, similarly to VCUG, diverticula may be missed if thick pus or debris prevents adequate filling with contrast medium or if the ostium is obstructed and prevents communication with the urethral lumen. Accordingly, although PPUG for many has been a primary tool for diagnosing urethral diverticula, it has gradually been replaced by other radiologic modalities due to the lack of necessary equipment and expertise and because of its associated patient discomfort and invasiveness.

SONOGRAPHY

This tool is a relatively new modality used to evaluate urethral diverticula, and has been shown to be effective (Gerrard, 2003). Suggested technical advantages of sonography in this setting include visualization of diverticula that did not fill during radiographic contrast studies and characterization of diverticular wall thickness, size, and internal architecture (Fig. 26-9) (Yang, 2005). In addition, Siegel and co-workers (1998) noted that sonography provided information on other lesions such as periurethral leiomyomas, diffuse urethritis, and periurethral scarring. Transabdominal, -vaginal, -rectal, -perineal, and urethral sonography have all been reported (Keefe, 1991; Vargas-Serrano, 1997). Although the advantages of sonography include patient comfort, avoidance of ionizing radiation and contrast exposure, relative low cost, and reduced invasiveness, its role in the diagnosis of urethral diverticula has not been clearly established. It remains an academic or adjunctive technique for now.

D = diverticulum; sp = symphysis pubis; U = urethra. *(From Yang, 2005, with permission.)*

MAGNETIC RESONANCE IMAGING

Within the last decade, the use of magnetic resonance (MR) imaging has become more common in the diagnosis of periurethral pathology, and is particularly useful in establishing the location, extent, and internal characteristics of periurethral masses (Kim, 1993; Nurenberg, 1997). For this reason, MR imaging is often recommended when diverticular architecture is complex, and its entire extent has not been delineated by other modalities (Daneshgari, 1999; Rovner, 2003; Vakili, 2003). In comparison with other imaging modalities, MR imaging has shown comparable or superior sensitivity for detecting urethral diverticula (Lorenzo, 2003; Neitlich, 1998). To improve image resolution, MR imaging may be used in conjunction with an imaging coil placed in the rectum or vagina. The coil, which is housed inside a probe, improves the image quality of structures surrounding the rectum or vagina (Blander, 2001). In spite of the advantages of MR imaging, procedure costs should be considered within the clinical context. For solitary diverticula with clearly demarcated boundaries and without extension, costly and extensive imaging is not necessary.

Because there is still no consensus on which modality should be used primarily, it is reasonable to begin with cystourethroscopic evaluation followed by VCUG. If the initial evaluation is unrevealing but the diagnostic suspicion remains high, then MR imaging with an endorectal coil may be informative.

Treatment

OBSERVATION

Many women with minimal or no symptoms may decline surgery due to its associated risks of urethrovaginal fistula and sphincter

defect incontinence. Long-term data on these women regarding rates of subsequent symptom development, diverticulum enlargement, and eventual need for surgical excision, however, are lacking.

SURGICAL

For many women, especially those with persistent symptoms, surgical correction is often indicated and procedures include diverticulectomy, marsupialization, and transvaginal partial ablation.

Of these procedures, diverticulectomy is the most commonly used and can be selected to treat diverticula at any site along the urethra (see Section 42-9, Urethral Diverticulum Repair). Vaginal excision of the entire diverticulum provides long-term correction of the urethral defect, normal urine stream, and high rates of postoperative continence. Disadvantages, however, include the risk of postsurgical urethral stenosis, urethrovaginal fistula, and potential injury of the urinary sphincter continence mechanism (Ljungqvist, 2007).

Alternatively, marsupialization of the diverticulum, also known as the Spence procedure, may be chosen to correct distal diverticula (Spence, 1970). The procedure is a meatotomy that when healed forms a new urethral meatus. Although simple to perform, this procedure alters the configuration of the meatus, and women often note a spray pattern with urination.

For proximal diverticula, partial ablation of the diverticular sac may be preferred to avoid the risk of bladder entry or bladder neck injury, which is associated with sacs in this location. Tancer and colleagues (1983) described this procedure, during which excess diverticular wall is excised vaginally, the diverticular neck is not removed, but remaining diverticular wall tissue is reapproximated to close the defect.

In addition to these approaches, case reports have described other procedures such as urethroscopic transurethral electrosurgical fulguration of the diverticular sac and transurethral incision to widen the diverticular ostia (Miskowiak, 1989; Saito, 2000; Vergunst, 1996). Data regarding long-term efficacy and complication rates with these techniques, however, are lacking.

PRINCIPLES OF CHEMOTHERAPY: INTRODUCTION

For the past 50 years, the incorporation of chemotherapy into the treatment of gynecologic cancers has been in a state of perpetual evolution. New advances develop frequently and pose a continual challenge to stay current in the field. Thus, a foundation for navigating the terminology of this important third component of cancer treatment is essential.

BIOLOGY OF CANCER GROWTH

In principle, drugs are able to treat cancer and spare normal cells by exploiting inherent differences in their individual growth patterns. Each tumor type has its own characteristics, which explains why the same chemotherapy regimen is not equally effective for the whole spectrum of gynecologic cancers. Selecting appropriate drugs and limiting the toxicity demands an understanding of the fundamentals of cellular kinetics.

The Cell Cycle

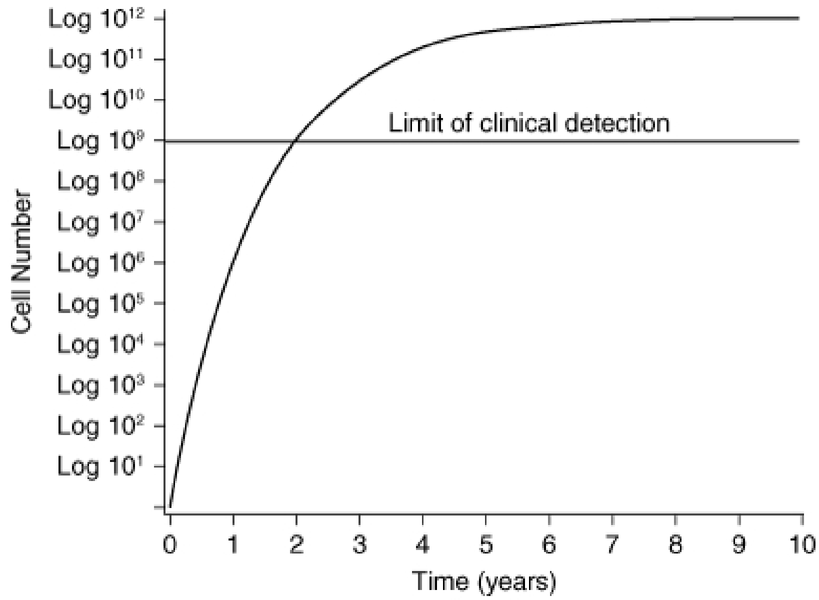
All dividing cells follow the same basic sequence for replication. The *cell generation time* is the length of time required to complete the five phases of the cell cycle (Fig. 28-8). The G_1 phase (G stands for gap) involves various cellular activities, such as protein synthesis, RNA synthesis, and DNA repair. When prolonged, the cell is considered to be in the G_0 , or resting, phase. G_1 cells may either terminally differentiate into the G_0 phase or re-enter the cell cycle after a period of quiescence. During the S phase, new DNA synthesis occurs. The G_2 (premitotic) phase is characterized by cells having twice the DNA content as they prepare for division. Finally, actual mitosis and chromosomal division takes place during the M phase.

Tumors *do not* have faster generation times, but instead have many more cells in the active phases of replication. In contrast, normal tissues have a much larger number of cells in the G_0 phase. As a result, cancer cells proceeding through the cell cycle are highly sensitive to chemotherapeutic agents, whereas normal cells in G_0 are protected. This growth pattern disparity underlies the effectiveness of chemotherapeutic agents.

Cancer Cell Growth

Tumors are characterized by a *gompertzian growth* pattern (Fig. 27-1). Fundamentally, a tumor mass requires progressively longer times to double in size as it enlarges. When a cancer is microscopic and nonpalpable, growth is exponential. However, as a tumor enlarges, the number of its cells undergoing replication decreases.

FIGURE 27-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

The gompertzian growth curve. During early stages of tumor expansion, growth is exponential, but with enlargement, tumor growth slows. Consequently, most tumors have completed their exponential growth phase at the time of clinical detection.

When tumors are in the exponential phase of gompertzian growth, they should be more sensitive to chemotherapy because a larger percentage of cells are in the active phase of the cell cycle. For this reason, metastases should be more sensitive to chemotherapy than a primary tumor. To take advantage of this potential benefit, advanced ovarian cancer is usually treated with surgical debulking and adjuvant chemotherapy. In addition, when a tumor mass shrinks in response to treatment, the presumption is that a greater number of cells will enter the active phase of the cell cycle to accelerate growth. This larger percentage of replicating cells should also increase the sensitivity of a tumor to chemotherapy.

Doubling Time

The time that it takes for a tumor to double in size is commonly referred to as its *doubling time.* Whereas the cell cycle generally refers to the activity of individual tumor cells, doubling time refers to the growth of an entire heterogenous tumor mass. In humans, the doubling times of specific tumors vary greatly.

The speed with which tumors grow and double in size is largely regulated by the number of cells that are actively dividing, known as the *growth fraction.* Typically, only a small percentage of the tumor will have cells that are rapidly proliferating. The remaining cells are in the G_0 resting phase. In general, tumors that are cured by chemotherapy are those with a high growth fraction, such as gestational trophoblastic neoplasia. When tumor volume is reduced by surgery or chemotherapy, the remaining tumor cells are theoretically propelled from the G_0 phase into the more vulnerable phases of the cell cycle, rendering them susceptible to chemotherapy.

Cell Kinetics

Chemotherapeutic agents work by first-order kinetics to kill a constant *fraction* of cells rather than a constant number. For example, one dose of a cytotoxic drug may result in a few logs (10^2 to 10^4) of cell kill, but not lead to a cure since tumor burden may be 10^{12} cells or more. Thus, the magnitude of cell kill necessary to eradicate a tumor typically requires intermittent courses of chemotherapy with more than one drug. Furthermore, first-order kinetics provides a rationale for surgical removal of large volume disease, followed by adjuvant chemotherapy to kill small tumor implants that contain 10^1 to 10^4 cells. In general, a cancer's

curability is inversely proportional to the number of viable tumor cells at the beginning of chemotherapy.

Some drugs achieve cell kill at several phases of the cell cycle. These *cell cycleâ€"nonspecific* agents, such as alkylating drugs, act in all phases of replication from G_0 to the M phase. *Cell cycleâ€"specific* agents act only on cells that are in a specific phase. By combining drugs that act in different phases of the cell cycle, the overall cell kill should be enhanced.

CLINICAL USE OF CHEMOTHERAPY

Clinical Setting

Chemotherapy may be used in four different ways (Table 27-1). The term *induction chemotherapy* is defined as primary treatment for patients with an advanced malignancy when no feasible alternative treatment exists. *Adjuvant chemotherapy* describes systemic treatment after a primary tumor has been controlled, but the risk of recurrence remains high. *Neoadjuvant chemotherapy* refers to drug treatment directed at an advanced cancer to decrease preoperatively the extent or morbidity of a subsequent surgical resection. Therapy applied to recurrent disease or to a tumor that is refractory to initial treatment is termed *salvage chemotherapy.*

Table 27-1 Different Clinical Settings for Delivering Chemotherapy

Categories	Examples within Gynecologic Oncology
Induction	Metastatic gestational trophoblastic neoplasia
Adjuvant	Platinum-based chemotherapy for advanced ovarian cancer after surgical debulking
Neoadjuvant	Primary platinum-based chemotherapy for advanced ovarian cancer that is initially unresectable
Salvage	Recurrent or persistent gynecologic cancer not amenable to curative surgery or radiation

Combination Therapy

With rare exceptions, single drugs administered at clinically tolerable doses do not cure cancer. Thus, in principle, combination chemotherapy provides maximum cell kill with minimal or tolerable adverse patient side effects. Drugs are selected based on their proven efficacy as single agents, different mechanisms of action, and minimally overlapping toxicities.

Combination chemotherapy is also more likely to attack heterogeneous populations of cells with different mechanisms of resistance. Moreover, the use of multiple drugs with different mechanisms of action tends to minimize the emergence of drug resistance. Usually, drugs used in any combination should have clinical data indicating that their effects will be synergistic or at least additive. Drugs in combination should be used at their optimal doses and schedules. Dose reductions initiated solely to aid the addition of other agents is counterintuitive.

Multimodality Treatment

Frequently, chemotherapy is combined with radiation therapy or sequenced with surgery to improve patient survival. For example, the standard of care for locally advanced cervical cancer has been transformed within the past decade by adding weekly cisplatin to standard radiotherapy. As a result, patients are more likely to survive due to enhanced radiosensitivity of the tumor and/or treatment of micrometastases outside the radiation field.

However, treatment-related toxicity is also increased. Patients previously treated with radiation therapy may have bone marrow, skin, or other body systems that are more susceptible to chemotherapy toxicity. As a result, dose reductions are commonplace. Furthermore, chemotherapy is generally less effective in tumors that are within a radiated field due to increased fibrosis and destruction of microcapillaries.

Combining chemotherapy with surgery has many different applications. For example, a woman with endometrial cancer may have nodal metastases detected during surgery, and receive postoperative pelvic radiation followed by combination chemotherapy. Alternatively, a woman with recurrent ovarian cancer may be treated by combination chemotherapy with or without preceding

secondary cytoreductive surgery. The purpose of sequencing treatment in this way is to augment chemotherapy effectiveness.

Goals of Treatment

In general, chemotherapy is used with either *curative* or *palliative intent* . When implementing chemotherapy with curative intent, there are typically only a defined number of courses. For instance, after tumor debulking, a woman with advanced ovarian cancer will usually achieve remission with six cycles of platinum-based chemotherapy. Emphasis is placed on maintaining curative dosages and treatment schedule. This often leads to significant toxicity, but for the possibility of achieving cure, these side effects are typically deemed acceptable.

Chemotherapy is often not used with curative intent, and the treating clinician must balance several factors to provide effective, compassionate palliation. Chemotherapy is selected to minimize disease progression and extend quality life. Thus, in this setting, greater importance is attached to avoiding excessive toxicity. In many ways, the use of chemotherapy for palliation exemplifies the "art" of medicine. Instead of a defined number of treatment courses, a clinician must frequently re-assess the treatment effectiveness and alter chemotherapy administration accordingly.

PHARMACOLOGIC PRINCIPLES

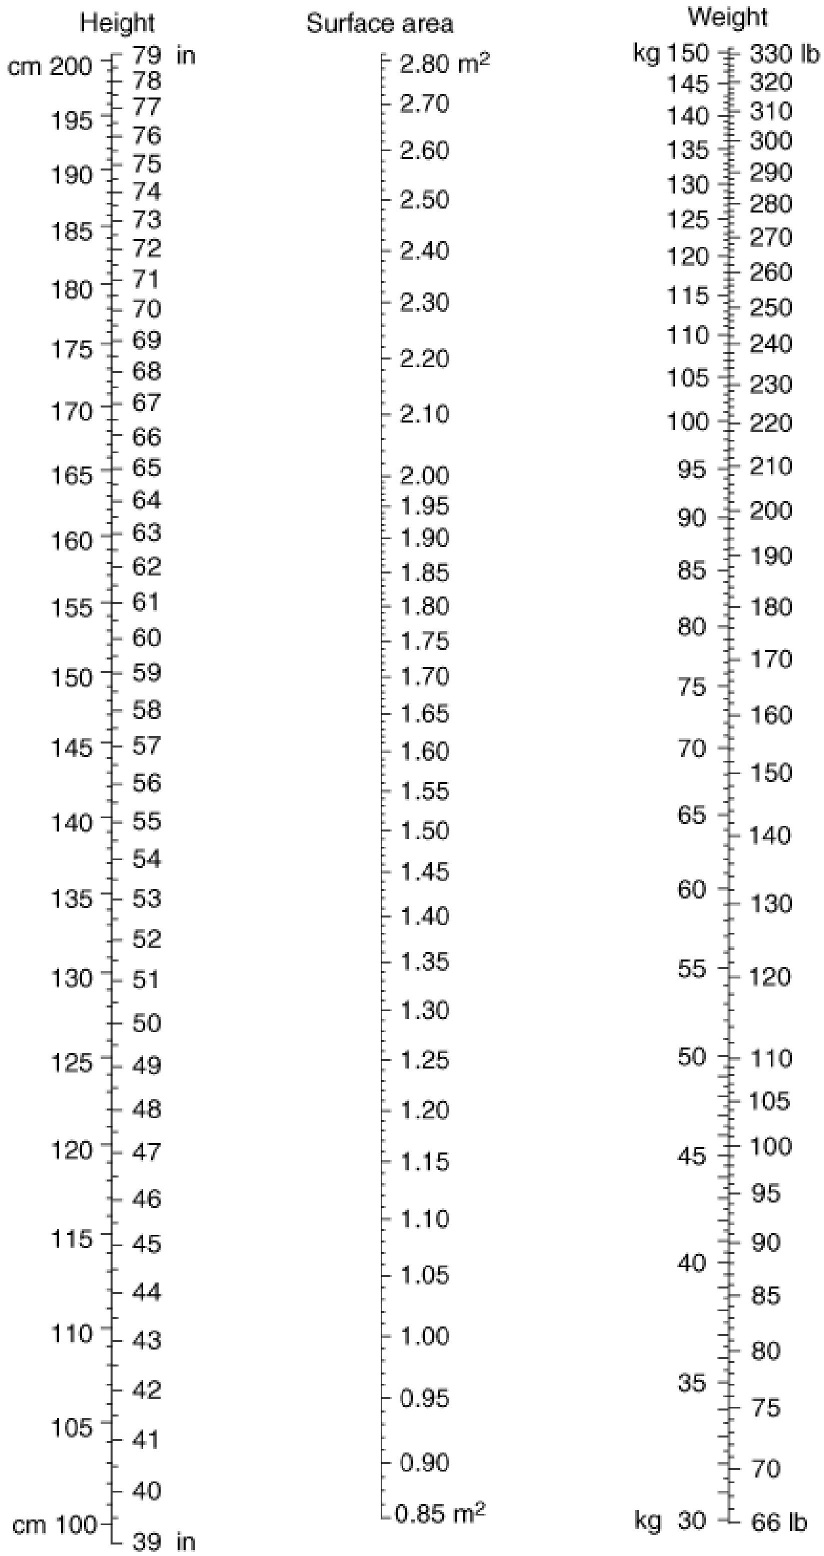
Various characteristics determine the appropriate use of chemotherapeutic drugs. Overall, treatment effectiveness depends on concentration and duration of exposure at critical tumor sites.

Drug Dosing

Chemotherapeutic agents typically have a narrow therapeutic range. Thus, doses must be calculated accurately to achieve an optimal effect and avoid undue toxicity.

Most commonly, chemotherapy dosages are calculated based on a patient's body surface area (BSA), expressed in milligrams per meter squared (mg/m^2). This modification normalizes for body frame and ensures that each patient receives proportionally similar amounts of drug. Heights and weights are obtained prior to every course of therapy. Edema or ascites must be determined, since dosages should be based on actual weight without these co-existing conditions. The BSA is most often calculated by using a nomogram (standard reference graph table) (Fig. 27-2).

FIGURE 27-2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Nomogram for calculating the body surface area (BSA) of adults. *(From DiSaia, 2002, with permission.)*

Alternatively, some drugs, such as bevacizumab, are dosed only by patient weight. In addition, carboplatin is dosed by a more complicated strategy, the Calvert formula, which includes a woman's glomerular filtration rate.

Dose Intensity

The amount of drug administered over time is known as the *dose intensity.* Its primary importance is in highly responsive tumors in which cure can be achieved with chemotherapy. However, in other less sensitive tumors, it may not be possible to increase the dose to a level sufficient to produce demonstrable benefit without producing dose-limiting toxicity. For example, trials using higher-dose chemotherapy with peripheral blood stem cell support have not improved outcomes in women with ovarian cancer. However, it is also true that reducing dose intensity to decrease toxicity can produce inferior therapeutic results.

Route of Administration

Chemotherapy may be administered systemically or regionally. Systemic therapy aims to attain maximal therapeutic cytotoxic effect without extreme toxicity to normal tissues. Oral, intravenous (IV) or intramuscular (IM) routes comprise systemic treatment options.

Regional chemotherapy is aimed at delivering drugs directly into the cavity in which the tumor is located. Clearance for many agents from a body cavity is slower than from systemic circulation. As a result, cancer cells are exposed longer to higher concentrations of active agents. This technique has been most extensively studied in ovarian cancer, in which tumors are usually confined to the intraperitoneal (IP) space. Clinical studies have uniformly demonstrated a pharmacologic advantage favoring administration into the IP compartment. However, penetration into peritoneal tumor nodules by passive diffusion is often limited by the presence of intra-abdominal adhesions, poor fluid circulation, fibrotic tumor encapsulation, and co-existing ascites. Because of these limitations in drug penetration, IP chemotherapy is typically administered to women with minimal residual disease.

During intravenous administration, several drugs are known vesicants that require special care (Table 27-2). Extravasation of these into the subcutaneous tissue can result in severe pain and necrosis. These drugs require slow infusion either through a rapidly flowing peripheral IV, or preferably via a central venous catheter. If extravasation is suspected, the infusion should be immediately stopped, the affected arm elevated, and cool packs applied. In severe cases, a plastic surgeon should be consulted.

Table 27-2 Chemotherapeutic Agents and Their Association with Extravasation Injury

Vesicants	Exfoliants	Irritants	Inflammants	Neutral
Dactinomycin	Cisplatin	Carboplatin	Methotrexate	Bleomycin
Doxorubicin	Docetaxel	Etoposide		Cyclophosphamide
Paclitaxel	Liposomal doxorubicin			Gemcitabine
Vinblastine	Topotecan			Ifosfamide
Vinorelbine				

Exfoliant, agent capable of causing skin exfoliation on extravasation; *inflammant,* agent capable of causing skin inflammation on extravasation; *irritant,* agent capable of causing skin irritation on extravasation; *vesicant,* agent capable of causing skin ulceration and tissue necrosis on extravasation.

Adapted from Mileshkin, 2004, with permission.

Excretion

Drug inactivation, elimination, or excretion dramatically influences activity and toxicity. For the most part, this takes place primarily via the liver or kidneys. As a result, drug activity may be diminished and toxicity exacerbated when there is impairment of normal liver or kidney function.

In addition, drug toxicity is often more pronounced in elderly patients or those who are malnourished. Thus, a low serum creatinine level in these women may not accurately reflect underlying renal function. If a carboplatin dose is calculated using this falsely low value, the amount may be excessive and result in considerable morbidity. Instead, a preset creatinine level may need to be selected (0.8 or 1.0 mg/dL) to aid safer dosing.

Drug Interactions

Most women who receive chemotherapy are often prescribed medication for other nonmalignant conditions, such as hypertension. Moreover, women also typically receive pain relievers, antiemetics, and antibiotics during chemotherapy. Most resultant drug interactions are probably of little consequence, but some may lead to substantially altered drug toxicity. Often drugs that are metabolized in the liver are at risk for such interactions. For example, using methotrexate in a woman taking warfarin will usually enhance the anticoagulant effect and thus requires a warfarin dose reduction.

Allergic Reaction

Despite reviewing a patient's history and administering prophylactic premedications, a woman may develop an anaphylactic, allergic, or hypersensitivity reaction during or after administration of chemotherapy. Accordingly, a treatment facility must have trained nursing staff and resources to manage these sudden but common issues.

Prior to drug administration, a woman should be informed of the necessity to report symptoms that may precede an anaphylactic reaction. Emergency equipment, such as supplemental oxygen, ventilatory face mask and bag (Ambu bag, Ambu, Glen Burnie, MD), or intubation equipment must be immediately available. For a localized hypersensitivity response, administration of diphenhydramine (Benadryl, Johnson & Johnson, New Brunswick, NJ) and/or steroids may be sufficient. However, for a generalized hypersensitivity or anaphylactic response, chemotherapy should be stopped immediately, an emergency team notified, and emergency drugs such as epinephrine (0.1 to 0.5 mg, 1:10,000 solution), administered (Table 27-3).

Table 27-3 Management of Hypersensitivity Reactions

1. Stop the chemotherapy infusion
2. Call a physician to assess the patient with regard to airway, breathing, and circulation
3. Administer intravenous normal saline if hypotensive
4. Administer oxygen if dyspneic or hypoxic
5. Administer intravenous antihistamine (e.g., 50 mg intravenous diphenhydramine or 25â€“50 mg intravenous promethazine)
6. Administer 5 mg of nebulized salbutamol if the patient has bronchospasm
7. Administer intravenous corticosteroids (e.g., 100 mg of hydrocortisone); this may have no effect on the initial reaction, but may prevent rebound or prolonged allergic manifestations
8. If the patient does not promptly improve or has symptoms of persistent or severe hypotension or persistent bronchospasm or laryngeal edema, administer adrenaline or epinephrine (0.1â€“0.25 mg intravenous); further acute resuscitation measures may be required
9. Reassure the patient that the problem is a recognized and treatable one
10. Consult a physician for a decision on further drug administration

From Mileshkin, 2004, with permission.

Drug Resistance

In principle, larger tumor masses have a greater proportion of cells that have already developed drug resistance. Resistance may be intrinsic or acquired, and it may develop to one drug or to multiple agents. In gynecologic oncology, intrinsic drug resistance is much less common. It is seen if tumors are first exposed to an agent and then fail to respond to initial treatment. In contrast, with acquired drug resistance, tumors no longer respond to drugs to which they were initially sensitive. Sometimes this occurs to a

specific drug. For instance, women with low-risk gestational trophoblastic neoplasia may become resistant to methotrexate, but remain exquisitely sensitive to dactinomycin. More often, however, acquired resistance is "pleiotropic", meaning that a cancer is resistant to multiple chemotherapy agents. Advanced ovarian cancer is a good example. Most patients will achieve remission with platinum-based chemotherapy, but 80 percent will ultimately relapse and die from tumors that have become resistant to all cytotoxic therapy.

Evaluating Response to Chemotherapy

The effective use of chemotherapy is a dynamic process whereby a treating clinician is constantly weighing toxicity to the patient against tumor response. In counseling women to continue treatment or switch to a different regimen, it is imperative to have objective criteria for response. The most important indicator is the *complete response rate* (Table 27-4). For ovarian cancer, this would include normal CA-125 levels, physical examination findings, and imaging test results. Ultimately, women who have any possibility of cure are those who first achieve a complete response. However, if chemotherapy results in a partial response, many women still view this as advantageous compared with supportive care, even if a survival benefit is unproven.

Table 27-4 Clinical End Points in Evaluating Response to Chemotherapy

End Point	Definition
Complete response	Complete resolution of all disease lasting for at least 1 month
Partial response	A decrease of ≥50 percent in the product of all measurable lesions lasting for at least 1 month without the development of new lesions
Stable disease	A decrease of <50 percent or an increase of <25 percent in the product of the diameters of all measurable disease
Progression	An increase of ≥25 percent in the measurable lesions as described above or the identification of new lesions

CHEMOTHERAPEUTIC DRUGS

In gynecologic oncology, diverse compounds that have demonstrated activity include antimetabolites, alkylating agents, antitumor antibiotics, plant alkaloids, taxanes, hormonal agents, and biologic therapies. These drugs may be used as single agents or in combination regimens.

Antimetabolites

The antimetabolites are structural and chemical analogs of naturally occurring substances in the metabolic pathways leading to the synthesis of purines, pyrimidines, and nucleic acids. In most cases, they are S phaseâ€"specific agents that are most effective in rapidly growing tumors associated with short doubling times and large growth fractions (Table 27-5).

Table 27-5 Chemotherapy Antimetabolites Used for Gynecologic Cancer					
Generic Name	**Brand Name**	**Indications**	**Routes**	**Common Dosages**	**Common Toxicity**
Methotrexate					
(MTX)	Trexall, Rheumatrex	GTN	PO, IM, IV, intrathecal	IM: 30-50 mg/m^2 IV: 100 mg/m^2 over 30 min, then 200 mg/m^2 over 12 h	BMD, mucositis, renal toxicity, CNS dysfunction
Gemcitabine	Gemzar	Recurrent ovarian CA, uterine sarcoma	IV	600-1000 mg/m^2 /wk over 30 min x 2-3 wks	BMD, N/V/D, malaise and fever

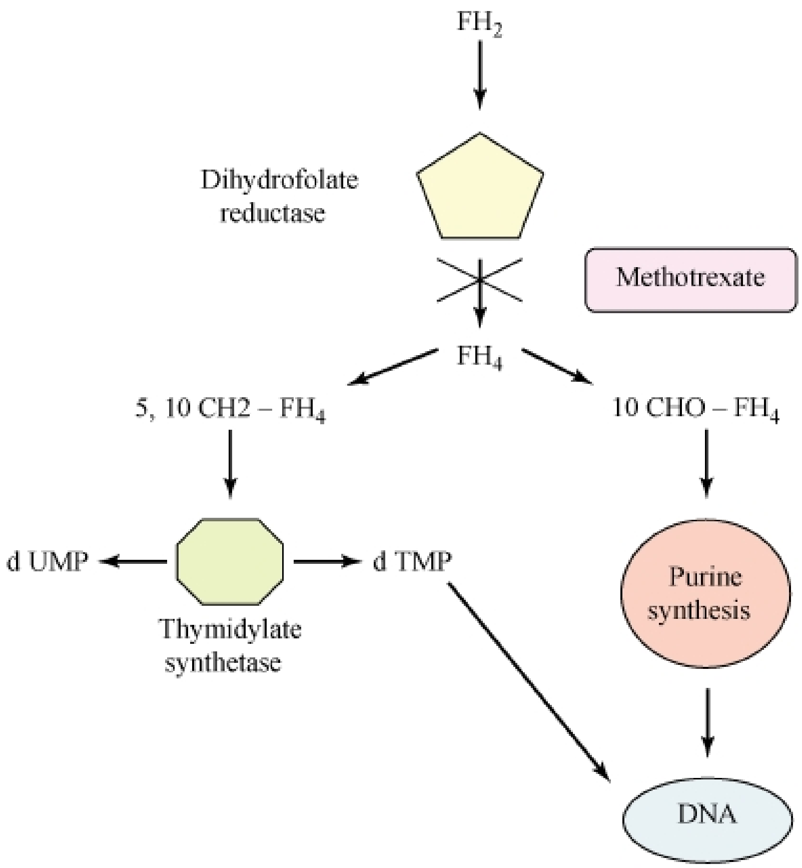
BMD = bone marrow depression; CA = cancer; CNS = central nervous system; GTN = gestational trophoblastic neoplasia; IM = intramuscular; IV = intravenous; N/A = not applicable; N/V/D = nausea, vomiting, and diarrhea; PO = orally.

METHOTREXATE

Mechanism of Action

This antimetabolite, also known as amethopterin, is most commonly used for treatment of women with gestational trophoblastic neoplasia (GTN) and ectopic pregnancy. Methotrexate (MTX) tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolic acid (the active form of folic acid) (Fig. 27-3). As a result, thymidylate synthetase and various steps in de novo purine synthesis are halted. This leads to arrest of DNA, RNA, and protein synthesis.

FIGURE 27-3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Methotrexate's primary target is the enzyme dihydrofolate reductase (DHFR). Inhibition of DHFR leads to partial depletion of the tetrahydrofolate cofactors, (5, 10 methylene tetrahydrofolic acid [5, 10 CH_2 -FH_4] and N-10 formyl tetrahydrofolic acid [10 CHO-FH_4]). These cofactors are required for the respective synthesis of thymidylate and purines. dTMP = deoxythymidine monophosphate; dUMP = deoxyuridine monophosphate.

Prescribing Information and Toxicity

Methotrexate may be administered orally, IM, IV, or intrathecally. Most commonly, MTX is given IM at 30 to 50 mg/m^2 weekly. Alternatively, 100 mg/m^2 IV over 30 minutes may be followed by a 200 mg/m^2 IV dose over 12 hours.

This agent causes minimal side effects at typical doses. However, at high doses, although used infrequently, MTX can lead to fatal bone marrow toxicity. This toxicity can be prevented by early administration of leucovorin (folinic acid), and this therapy is termed *leucovorin rescue.* Rescue is typically required for MTX doses over 80 mg/m^2 . With it, up to 100 mg/m^2 of leucovorin is given every 6 hours and is usually begun within 4 hours after completing MTX treatment. Further leucovorin dosing may be adjusted according to serum methotrexate levels.

In addition to myelosuppression, renal toxicity and acute cerebral dysfunction are typically only seen at high doses. Methotrexate is predominantly excreted through the kidneys, and thus women with renal insufficiency should have dosages reduced.

GEMCITABINE

Mechanism of Action

This antimetabolite is typically selected for treatment of recurrent ovarian cancer and uterine sarcomas. Gemcitabine (Gemzar, Eli Lilly, Indianapolis, IN) is a synthetic nucleoside analog that undergoes multiple phosphorylations to form the active metabolite. The resulting triphosphate is subsequently incorporated into DNA as a fraudulent base pair. Following the insertion of gemcitabine, one

additional deoxynucleotide is added to the end of the DNA chain before replication is terminated, and thereby DNA synthesis is halted.

Prescribing Information and Toxicity

The usual administration of gemcitabine is by 30-minute infusion. Durations of greater than 60 minutes are associated with dose-limiting flu-like symptoms. Depending on whether it is used as a single agent or in combination, gemcitabine is typically given between 600 to 1000 mg/m^2 once weekly for 2 to 3 weeks followed by a week of rest.

Myelosuppression, especially neutropenia, is the main dose-limiting side effect. Gastrointestinal (GI) toxicity, such as nausea, vomiting, diarrhea, or mucositis is also common. About 20 percent of patients will develop a flu-like syndrome, including fever, malaise, headache, and chills. Pulmonary toxicity is relatively uncommon, but reported.

Alkylating Agents

The alkylating agents are characterized by positively charged alkyl groups that bind to negatively charged DNA to form adducts (Table 27-6). Binding leads to DNA breaks or cross-links and a halt of DNA synthesis. In general, these drugs are cell cycleâ€"nonspecific agents that work at any phase of active replication.

Table 27-6 Chemotherapy Alkylating Agents Used for Gynecologic Cancer

Generic Name	Brand Name	Indication	Routes	Dosages	Toxicity
Cyclophosphamide	Cytoxan	GTN, recurrent ovarian CA	PO, IV	IV: 500-750 mg/m^2 over 30 min, every 3 wks	BMD, cystitis, N/V, alopecia
Ifosfamide	Ifex	Recurrent ovarian CA, cervical CA, uterine sarcoma	IV	1.2-1.6 g/m^2 /d on days 1-3 of 3-wk cycle	BMD, cystitis, N/V, alopecia, CNS and renal toxicity

BMD = bone marrow depression; CA = cancer; CNS = central nervous system; GTN = gestational trophoblastic neoplasia; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PO = orally.

CYCLOPHOSPHAMIDE

Mechanism of Action

This alkylating agent is infrequently used, and its chief role is as part of combination chemotherapy. Cyclophosphamide is the "C" of the EMA-CO (etoposide, methotrexate, Adriamycin D, cyclophosphamide, and Oncovin [vincristine]) regimen prescribed for GTN or used as single-agent salvage therapy for recurrent epithelial ovarian cancer (Bower, 1997; Cantu, 2002). Cyclophosphamide (Cytoxan, Bristol-Myers Squibb, New York, NY) is a derivative of nitrogen mustard and is activated by a multistep process by microsomal enzymes in the liver. Its action results in DNA cross-linking and inhibition of DNA synthesis.

Prescribing Information and Toxicity

Cyclophosphamide is typically given IV at 500 to 750 mg/m^2 over 30 minutes every 3 weeks. Following administration, myelosuppression, mainly neutropenia, is the usual dose-limiting side effect. This agent is exclusively excreted by the kidneys, and hemorrhagic cystitis is a classic complication that may be delayed from 24 hours to several weeks after administration. To prevent this effect, adequate hydration is imperative to aid excretion of the metabolite acrolein, which can alkylate the bladder mucosa. In addition, GI toxicity, such as nausea, vomiting, or anorexia, is common. Alopecia is typically severe. Moreover, secondary malignancies are increased, particularly acute myelogenous leukemia and bladder cancer.

IFOSFAMIDE

Mechanism of Action

This alkylating agent is typically administered in salvage treatment of recurrent epithelial ovarian cancer, cervical cancer, and uterine sarcoma. Ifosfamide (Ifex, Bristol-Myers Squibb) is a structural analog of cyclophosphamide, differing only slightly.

However, its metabolic activation occurs more slowly than that of cyclophosphamide and leads to a greater production of chloracetaldehyde, a possible neurotoxin.

Prescribing Information and Toxicity

Ifosfamide is administered IV, usually as a short infusion. Common dosages of 1.2 to 1.6 g/m^2 are given on days 1 through 3 of a 3-week cycle. As with cyclophosphamide, adequate hydration is recommended to reduce the incidence of drug-induced hemorrhagic cystitis. In addition, the use of concurrent mesna (Mesnex, Bristol-Myers Squibb) is required to prevent severe hematuria. A metabolite of mesna chemically binds with the urotoxic ifosfamide metabolite, acrolein, and detoxifies it.

Overall, side effects are similar to those of cyclophosphamide. However, neurotoxicity, manifested as lethargy, confusion, seizure, ataxia, hallucinations, and occasionally coma, are more likely. These symptoms are caused by the chloracetaldehyde metabolite and are spontaneously reversible.

Antitumor Antibiotics

The antitumor antibiotics are generally derived from microorganisms. Most antitumor antibiotics exert their cytotoxic effects by DNA intercalation, and as a group, they are cell-cycle nonspecific.

DACTINOMYCIN

Mechanism of Action

This agent is used to treat GTN as a single agent or as part of combination chemotherapy (Table 27-7). Dactinomycin (Cosmegen, Merck & Co., Whitehouse Station, NJ), also known as Adriamycin D, is the "A" of the EMA-CO chemotherapy combination. Dactinomycin is a product of the genus *Streptomyces* and becomes anchored into purine-pyrimidine DNA base pairs, resulting in inhibition of DNA synthesis. Toxic oxygen-free radicals also cause DNA breaks. Dactinomycin is mainly excreted through the biliary system.

Table 27-7 Chemotherapeutic Antibiotics Used for Gynecologic Cancer

Generic Name	Brand Name	Indication	Route	Dosage	Toxicity
Actinomycin D (dactinomycin)	Cosmegen	GTN	IV	1.25 mg IV push every other wk or 0.5 mg on days 1-5, every 2-3 wks	BMD, N/V/D, alopecia, vesicant
Bleomycin	Blenoxane	Germ cell or SCST ovarian CA, GTN	IV, IM, SC, intrapleurally	IV: 20 U/m^2 (maximum dose of 30 U), every 3 wks	Pulmonary toxicity, fever, skin reaction
Doxorubicin	Adriamycin	Endometrial CA, recurrent epithelial ovarian CA	IV	45-60 mg/m^2 every 3 wks	BMD, cardiac toxicity, alopecia, vesicant
Liposomal doxorubicin	Doxil	Recurrent epithelial ovarian CA	IV	40-50 mg/m^2 over 30 min, every 4 wks	PPE, stomatitis, infusion reaction

BMD = bone marrow depression; CA = cancer; GTN = gestational trophoblastic neoplasia; IM = intramuscular; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PPE = palmar-plantar erythrodysesthesia; SC = subcutaneous; SCST = sex cord-stromal tumor.

Prescribing Information and Toxicity

The usual "pulse" dose of dactinomycin is 1.25 mg IV push every other week or 0.5 mg on days 1 through 5 every 2 to 3 weeks. Myelosuppression is the main dose-limiting side effect and it may be severe. Moreover, GI toxicity, including nausea, vomiting, mucositis, and diarrhea are often significant. Alopecia is common. As with others in the antibiotic group, dactinomycin is a potent

vesicant that can cause skin ulceration and tissue necrosis if extravasated during IV infusion (Route of Administration).

BLEOMYCIN

Mechanism of Action

This antitumor antibiotic is the "B" in BEP (bleomycin, etoposide, and cisplatin) regimens, which are used as adjuvant treatment of malignant ovarian germ cell or sex cord-stromal tumors (Homesley, 1999; Williams, 1991). Additionally, it is used in salvage treatment of GTN (DuBeshter, 1989).

Bleomycin (Blenoxane, Bristol-Myers Squibb), when complexed with iron, creates activated oxygen-free radicals, which cause DNA strand breaks and cell death. It is cell-cycle specific and maximally effective during the G_2 phase.

Prescribing Information and Toxicity

The usual dose of bleomycin is 20 U/m^2 IV (maximum dose of 30 units), given every 3 weeks. The dosage is quantitated in international units of cytotoxic activity. Bleomycin can also be administered by the IM, subcutaneous (SC), or intrapleural routes.

Pulmonary toxicity is the main dose-limiting side effect, developing in 10 percent of patients. Accordingly, for women prescribed bleomycin, chest radiographs and clinical auscultation should be performed regularly. Typically, pneumonitis with cough, dyspnea, dry inspiratory crackles, and infiltrates on chest radiograph result. This complication is more common in patients older than 70 years and with cumulative doses of greater than 400 units. Pulmonary function tests (PFTs) with special focus on carbon monoxide diffusion in the lung (DL_{CO}) and vital capacity should be obtained at baseline and during therapy. A 15-percent decrease in pulmonary function requires discontinuation of bleomycin. In addition to pulmonary effects, skin reactions with bleomycin are common, but this drug is not myelosuppressive.

DOXORUBICIN

Mechanism of Action

This antitumor antibiotic is the "A" in the combination chemotherapy TAP (taxol, Adriamycin, and cisplatin), used for endometrial cancer. Doxorubicin (Adriamycin, Pfizer, New York, NY) is also used for recurrent epithelial ovarian cancer.

This agent intercalates into DNA to inhibit DNA synthesis, inhibits topoisomerase II, and forms cytotoxic oxygen-free radicals. The drug is metabolized extensively in the liver and eliminated through biliary excretion.

Prescribing Information and Toxicity

The usual dose of doxorubicin is 45 to 60 mg/m^2 IV as part of combination chemotherapy, repeated every 3 weeks. Myelosuppression, particularly neutropenia, is the main dose-limiting side effect. However, cardiotoxicity is a classic complication. Patients should be monitored with a multiple gated acquisition (MUGA) radionuclide scan at baseline and periodically during therapy. The risk of cardiotoxicity is higher in women older than 70 years and those with cumulative doses exceeding 550 mg/m^2 . Ultimately, women may develop a dilated cardiomyopathy associated with congestive heart failure. Gastrointestinal toxicities are generally mild, but alopecia is universal.

LIPOSOMAL DOXORUBICIN

Mechanism of Action

This antitumor antibiotic is used in salvage treatment of recurrent epithelial ovarian cancer (Gordon, 2004). The liposomal encapsulation of doxorubicin (Doxil, Ortho Biotech, Bridgewater, NJ) dramatically alters the pharmacokinetic and toxicity profiles of the drug. Researchers developed liposomal doxorubicin to reduce cardiotoxicity and to selectively target the drug to tumor tissues.

Prescribing Information and Toxicity

Liposomal doxorubicin may be administered as an IV infusion over 30 to 60 minutes and is dosed at 40 to 50 mg/m^2 every 4 weeks. Administration is associated with minimal nausea, vomiting, alopecia, and cardiotoxicity. Infusion-related reactions develop in less than 10 percent of patients and are most common during the first course of treatment. However, an increased rate of stomatitis and palmar-plantar erythrodysesthesia (PPE) is noted. At first, PPE causes redness and dysesthesias of the palms and

soles. Initial tingling sensations may advance to discomfort, and distal extremity swelling may be noted. As toxicity progresses, ulceration within extremity skin creases and desquamation may follow.

Plant-Derived Agents

A common theme in the cytotoxic activity of these agents is disturbance of normal assembly, disassembly, and stabilization of intracellular microtubules. The group includes the taxanes, vinca alkaloids, and topoisomerase inhibitors.

TAXANES

Paclitaxel and docetaxel are both cell cycleâ€"specific agents that have maximal activity during the M phase (Table 27-8). They act to "poison" the mitotic spindle by preventing depolymerization of the microtubules and inhibiting cellular replication. Paclitaxel is derived from the needles and bark of the western yew, *Taxus brevifolia.* Docetaxel is a semi-synthetic analog of paclitaxel derived from the European yew tree.

Table 27-8 Chemotherapeutic Plant Alkaloids Used for Gynecologic Cancer

Generic Name	Brand Name	Indications	Routes	Dosages	Toxicity
Paclitaxel	Taxol	Recurrent epithelial ovarian CA, endometrial CA, cervical CA, GTN	IV	135-175 mg/m^2 every 3 wks	HSR, peripheral neurotoxicity, BMD, alopecia, bradycardia and arrhythmia
Docetaxel	Taxotere	Recurrent epithelial ovarian CA, uterine sarcoma	IV	75-100 mg/m^2 every 3 wks	BMD, peripheral edema, HSR, alopecia
Vincristine	Oncovin	GTN	IV	0.8-1.0 mg/m^2 every other wk	Neurotoxicity, abdominal pain, alopecia
Vinblastine	Velban	GTN	IV	9 mg/m^2 every 3 wks	BMD, N/V/D, mucositis, HTN, neurotoxicity, alopecia
Vinorelbine	Navelbine	Recurrent epithelial ovarian CA, cervical CA	IV	30 mg/m^2 every wk	BMD, N/V/D, stomatitis, peripheral neurotoxicity
Etoposide	VP-16	Germ cell or SCST ovarian CA; recurrent epithelial ovarian CA; endometrial CA	IV, PO	IV: 75 mg/m^2 , days 1-5, every 3 wks	BMD, alopecia, secondary cancers
Topotecan	Hycamtin	Recurrent epithelial ovarian CA, cervical CA	IV	1.5 mg/kg/d, days 1-5, every 3 wks	BMD, N/V, alopecia, fever, malaise

BMD = bone marrow depression; CA = cancer; GTN = gestational trophoblastic neoplasia; HSR = hypersensitivity reaction; HTN = hypertension; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PO = orally; SCST = sex cord-stromal tumor.

Paclitaxel

One of the most widely used agents, paclitaxel (Taxol, Bristol-Myers Squibb) is used for treatment of primary or recurrent epithelial ovarian, endometrial, and cervical cancers, and GTN.

Prescribing Information and Toxicity

Paclitaxel's usual dose is 135 to 175 mg/m^2 given IV over 3 hours, every 3 weeks. For recurrent ovarian cancer, weekly paclitaxel is also effective at 80 mg/m^2 IV for 3 consecutive weeks on a 28-day schedule (Markman, 2006).

Myelosuppression is the usual dose-limiting side effect. In addition, a hypersensitivity reaction occurs in about one third of patients due to its formulation in Cremophor-EL (BASF, Florham Park, NJ), an emulsifying agent. Typically, the reaction develops within

minutes of starting an initial infusion. Fortunately, the incidence can be decreased 10-fold by premedication with steroids, usually dexamethasone, 20 mg orally 12 and 6 hours before administration. Neurotoxicity is the principal nonhematologic dose-limiting side effect. Common symptoms include numbness, tingling, and/or burning pain in a stocking-glove distribution. Peripheral neuropathy progresses with increased paclitaxel exposure and may become debilitating. Alopecia is almost universal and results in total loss of body hair.

Docetaxel

This taxane may be used to treat recurrent epithelial ovarian cancer and uterine sarcoma (Bay, 2006; Strauss, 2007). In addition, patients with worsening neurotoxicity with paclitaxel are often switched to docetaxel since clinical efficacy is thought to be similar.

Prescribing Information and Toxicity

The usual dose of docetaxel (Taxotere, Sanofi-Aventis, Bridgewater, NJ) is 75 to 100 mg/m^2 IV, repeated every 3 weeks. For recurrent ovarian cancer, weekly docetaxel is also effective at 35 mg/m^2 IV for 3 consecutive weeks on a 28-day schedule (Tinker, 2007).

Myelosuppression is the main dose-limiting side effect. Fluid retention syndrome occurs in about half of patients, manifesting as weight gain, peripheral edema, pleural effusion, and ascites. Steroid prophylaxis prevents most of this toxicity, as well as dermatologic side effects and hypersensitivity reactions.

VINCA ALKALOIDS

Vincristine, vinblastine, and vinorelbine are cell cycleâ€"specific drugs derived from the periwinkle plant with maximal activity in the M phase. These compounds inhibit normal microtubular polymerization by binding to the tubulin subunit at a site distinct from the taxane-binding site.

Vincristine

This vinca alkaloid represents the "O" of EMA-CO combination chemotherapy for GTN treatment. The usual dose of vincristine (Oncovin, Eli Lilly) is 0.8 to 1.0 mg/m^2 , given IV every other week. To prevent or delay the development of neurotoxicity, the total individual dose should be capped at 2 mg.

Neurotoxicity is the most common dose-limiting toxicity, and may include peripheral neuropathy, autonomic nervous system dysfunction, cranial nerve palsies, ataxia, or seizures. Moreover, concurrent administration with other neurotoxic agents such as cisplatin and paclitaxel may increase severity. Gastrointestinal toxicity is also common, including constipation, abdominal pain, and paralytic ileus. However, myelosuppression is typically mild.

Vinblastine

This vinca alkaloid may be used in salvage treatment for GTN. The usual dose of vinblastine (Velban, Eli Lilly) varies, but one approach administers 9 mg/m^2 IV every 3 weeks. This agent is toxic and as a result, not commonly used. Myelosuppression is the main dose-limiting side effect. Gastrointestinal toxicity may be severe and includes mucositis, stomatitis, nausea, vomiting, anorexia, and diarrhea or constipation. In addition, hypertension may result from autonomic dysfunction. Neurotoxicity develops much less frequently, but is similar to that seen with vincristine.

Vinorelbine

This vinca alkaloid is a semisynthetic derivation of vinblastine and is used in salvage treatment for recurrent epithelial ovarian cancer and for treatment of cervical cancer. The usual dose of vinorelbine (Navelbine, GlaxoSmithKline, Philadelphia, PA) is 30 mg/m^2 given IV, as a single agent or in combination. It is given on a weekly basis, with a week off in a 21- or 28-day schedule.

Myelosuppression is the main dose-limiting side effect. Moreover, GI toxicity is common and has symptoms similar to those of vinblastine. Neurotoxicity is usually mild, particularly compared with other vinca alkaloids.

TOPOISOMERASE INHIBITORS

The topoisomerase (TOPO) inhibitors are semisynthetic cytotoxic agents derived from the mandrake plant. This group of agents

may be further divided into categories based on the TOPO enzyme they inhibit. The podophyllotoxins are those that inhibit TOPO II and include etoposide. The camptothecins inhibit TOPO I and include topotecan.

ETOPOSIDE

Mechanism of Action

This agent is often used intravenously as part of combination chemotherapy. Etoposide represents the "E" of the EMA-CO regimen, which is used for GTN. In addition, it is a component of the BEP regimen, used for ovarian germ cell or sex cord-stromal tumors. Oral etoposide may be efficacious as a single agent for salvage treatment of recurrent epithelial ovarian cancer or endometrial cancer.

Etoposide (VP-16, Bristol-Myers Squibb) is a cell cycleâ€"specific agent with maximal activity in the late S and G_2 phase. This drug "poisons" the TOPO II enzyme by stabilizing an otherwise transient form of the TOPO II-DNA complex. As a result, DNA cannot unwind.

Prescribing Information and Toxicity

The usual dose of etoposide varies. In the EMA-CO regimen, 100 mg/m^2 is administered IV on days 1 and 2, every 2 weeks. In the BEP regimen, it is usually prescribed as 75 mg/m^2 IV on days 1 through 5, and given every 3 weeks. The oral dose is 50 mg/m^2 /d for a 21-day course, followed by a week off on a 28-day schedule. Up to 95 percent of etoposide is protein-bound, mainly to albumin. Thus, decreased albumin levels result in a higher fraction of free drug and potentially a higher incidence of toxicity.

Myelosuppression, most commonly neutropenia, is the main dose-limiting side effect with etoposide. Gastrointestinal symptoms of nausea, vomiting, and anorexia are usually minor, except with oral administration. Most patients will develop alopecia. With etoposide, there is an increased risk of secondary malignancies, especially acute myelogenous leukemia, particularly if the total dose exceeds 2,000 mg/m^2 .

TOPOTECAN

Mechanism of Action

This agent is a semisynthetic analog of the alkaloid extract camptothecin and inhibits TOPO I function. It binds to and stabilizes a transient TOPO I-DNA complex, resulting in double-strand breakage and lethal DNA damage. Topotecan (Hycamtin, GlaxoSmithKline) is used in salvage therapy of recurrent epithelial ovarian cancer and recurrent cervical cancer (Long, 2005).

Prescribing Information and Toxicity

Topotecan is administered IV, by two different schedules. The standard dosage for recurrent ovarian cancer is 1.5 mg/m^2 for days 1 through 5, given every 3 weeks (Gordon, 2004). However, this schedule is associated with a greater than 80-percent incidence of severe neutropenia. A less toxic regimen is 4 mg/m^2 weekly for 3 weeks during a 28-day schedule (Spannuth, 2007). The usual dose when combined with cisplatin for recurrent cervical cancer is 0.75 mg/m^2 on days 1 through 3, given every 3 weeks (Long, 2005).

Myelosuppression, most commonly neutropenia, is the main dose-limiting side effect. Gastrointestinal toxicity is also common, and includes nausea, vomiting, diarrhea, and abdominal pain. Systemic symptoms such as headache, fever, malaise, arthralgias, and myalgias are typical. Alopecia is often as complete as that seen with paclitaxel therapy.

Miscellaneous

Several antineoplastic compounds do not clearly fit into any of the above categories. In general, these cell cycleâ€"nonspecific drugs have similarities to alkylating agents.

CARBOPLATIN

Mechanism of Action

This agent is one of the most widely used, particularly in adjuvant or salvage treatment of epithelial ovarian and endometrial cancers. Carboplatin (Paraplatin, Bristol-Myers Squibb) produces DNA adducts that inhibit DNA synthesis.

Prescribing Information and Toxicity

The usual IV dose of carboplatin is calculated to a target area under the curve (AUC) of 6, based on the glomerular filtration rate (GFR). For dose calculation, the Calvert equation is the most frequently used [carboplatin total dose (mg) = AUC x (GFR + 25)]. In clinical practice, the estimated creatinine clearance (CrCl) is usually substituted for the GFR and may be calculated by the Cockcroft-Gault equation [CrCl = (140 â€“ age) x weight (kg)/0.72 x serum creatinine level (mg/100 mL)]. The infusion takes about 30 minutes and dosing is repeated every 3 weeks.

Myelosuppression, most commonly thrombocytopenia, is the main dose-limiting side effect. Gastrointestinal toxicity and peripheral neuropathy are notably less compared with cisplatin. Hypersensitivity reactions will eventually develop in up to 25 percent of women receiving more than six cycles.

CISPLATIN

Mechanism of Action

Similar to carboplatin, this agent produces DNA adducts that inhibit DNA synthesis (see Fig. 28-11). Cisplatin (CDDP, Bristol-Myers Squibb) is one of the most widely used agents. It may be given concomitantly with radiation as a radiosensitizing agent for primary treatment of cervical cancer, or either as a single agent or in combination for recurrent cervical cancer. For ovarian germ cell or sex cord-stromal tumors, cisplatin is part of combination chemotherapy as the "P" of BEP. It is also a member of combination chemotherapy as the "P" of TAP for advanced or recurrent endometrial cancer. However, for use in epithelial ovarian cancer, cisplatin has largely been replaced by carboplatin, except for IP therapy.

Prescribing Information and Toxicity

The usual dose of cisplatin varies, depending on the indication. In cervical cancer, it is given at 40 mg/m^2 IV weekly during radiation therapy, or 50 mg/m^2 IV every 3 weeks for patients with recurrent disease (Long, 2005). The 50-mg/m^2 dose is also used in the TAP regimen every 3 weeks (Fleming, 2004). As part of the BEP protocol, cisplatin is administered 20 mg/m^2 IV on days 1 through 5 every 3 weeks. Alternatively, for ovarian cancer IP chemotherapy, it is given on day 2 of a 21-day cycle at a dosage of 75 to 100 mg/m^2 (Armstrong, 2006).

Cisplatin has several significant adverse effects associated with administration. Of these, nephrotoxicity is the main dose-limiting side effect. Accordingly, patients must be aggressively hydrated before, during, and after drug administration. Mannitol (10 g) or furosemide (20 to 40 mg) may be necessary to maintain a urine output of at least 100 to 150 mL/h. With cisplatin administration, electrolyte abnormalities, such as hypomagnesemia and hypokalemia, are common. In addition, severe, prolonged nausea and vomiting can be dramatic without adequate premedication (Table 27-9). Patients often describe a metallic taste and loss of appetite following treatment. Neurotoxicity, usually in the form of peripheral neuropathy, can also be dose limiting and irreversible. Ototoxicity typically manifests as high-frequency hearing loss and tinnitus. Similarly to carboplatin, hypersensitivity reactions may develop, and overall cisplatin is significantly more toxic than carboplatin.

Table 27-9 Dose and Schedule of Antiemetics to Prevent Emesis Induced by Antineoplastic Therapy of High Emetic Risk			
Antiemetics for Intravenous Antineoplastic Therapy of Moderate Emetic Risk	**Brand Name**	**Single Dose Administered Before Chemotherapy**	**Single Dose Administered Daily**
5-HT_3 serotonin receptor antagonists			
Granisetron	Kytril	Oral: 2 mg IV: 1 mg or 0.01 mg/kg	
Ondansetron	Zofran	Oral: 24 mg IV: 8 mg or 0.15 mg/kg	
Palonosetron	Aloxi	IV: 0.25 mg	
Dexamethasone	Decadron	Oral: 12 mg	Oral: 8 mg, days 2-4
Aprepitant	Emend	Oral: 125 mg	Oral: 80 mg, days 2 and 3

5-HT_3 = 5-hydroxytryptamine-3; IV = intravenous.

Adapted from Kris, 2006, with permission.

HEXAMETHYLMELAMINE

This agent forms DNA cross-links, but its exact chemotherapeutic mechanism of action is unknown. Hexamethylmelamine, also called altretamine (Hexalen, MGI Pharma, Bloomington, MN), is used in consolidation therapy of advanced epithelial ovarian cancer and in salvage treatment of recurrent epithelial ovarian cancer (Alberts, 2004; Rustin, 1997).

The usual dose of hexamethylmelamine is 260 mg/m^2 daily, given as four divided oral doses for 14 to 21 consecutive days in a 28-day cycle. Gastrointestinal side effects, such as nausea and vomiting, are the usual dose-limiting toxicity. Myelosuppression is also common. In addition, approximately one quarter of patients will develop neurotoxicity, manifested as lethargy, agitation, or peripheral neuropathy.

Hormonal Agents

Due to their minimal toxicity and reasonable activity, hormonal agents are commonly used for the treatment of endometrial, ovarian, and breast cancers.

TAMOXIFEN

This drug is a nonsteroidal anti-estrogen that competes for binding to the estrogen receptor. The complex is then transported to the tumor cell nucleus, where it binds to DNA and inhibits cellular growth and proliferation. As such, tamoxifen (Nolvadex, AstraZeneca, Wilmington, DE) is indicated in the treatment of endometrial cancer and recurrent epithelial ovarian cancer (Fiorica, 2004; Markman, 2004). It is usually prescribed in dosages of 20 to 40 mg orally daily. The toxicity associated with tamoxifen in minimal, but menopausal symptoms are common. Moreover, fluid retention and peripheral edema develop in one third of patients.

MEGESTROL ACETATE

This agent is a synthetic derivative of progesterone that has activity on tumors through its anti-estrogenic effects. As such, megestrol acetate (Megace, Bristol-Myers Squibb) is used to treat recurrent endometrial cancer, and the usual dosage is 40 mg orally, four times daily.

This drug has minimal toxicity. However commonly patients gain weight from a combination of fluid retention and increased

appetite.

BIOLOGICAL THERAPY

Although this field is still in its infancy, biological therapy is designed to more accurately target specific tumors while avoiding much of the toxicity seen in conventional chemotherapy. This approach is often referred to as *immunotherapy* or *biological response modifier therapy.* Such novel therapeutic designs may enhance the chemosensitivity of malignant cells to treatment or may use the body's own immune system to attack the cancer. Many new treatments are currently being tested. Ultimately, the long-term goal is to improve cancer patient outcome, especially in those with tumors that are resistant to standard therapy.

Bevacizumab

This agent is a monoclonal antibody that works as an anti-angiogenic agent. Currently, the use of bevacizumab (Avastin, Genentech, South San Francisco, CA) is investigational and indicated primarily in heavily pretreated recurrent epithelial ovarian cancer (Wright, 2006). Its usual dose is 15 mg/kg IV, given every 3 weeks with or without cytotoxic chemotherapy. In most cases, the toxicity with bevacizumab is minimal. However, GI perforation occurs in up to 10 percent of patients. Elevated blood pressure is common and may lead to hypertensive crisis. Other possible toxicities include incomplete wound healing, weakness, pain, nosebleed, or proteinuria.

Oregovamab

This monoclonal antibody was designed to bind with high affinity to CA125, and thereby help the immune system recognize and attack ovarian cancers. Oregovamab (OvaRex, Unither Pharamaceuticals, Wellesley Hills, MA) is currently under investigation for the treatment of epithelial ovarian cancer. Its usual dose is 2 mg IV, given as a short infusion, several times per year. This therapy has minimal toxicity, but pain, myalgia, arthralgia, and diarrhea have been reported (Berek, 2004).

VACCINES

Therapeutic cancer vaccines are designed to induce cellular components of the immune system to recognize and attack tumors. Malignant cells that express specific surface antigens can thereby be targeted and destroyed. For example, in cervical cancer, viral peptides derived from human papillomavirus (HPV) E6 and E7 oncoproteins have been clinically tested (Borysiewicz, 1996). Additionally, ovarian cancer patients have been studied with a vaccine directed at CA125 (Reinartz, 2004).

For the most part, such strategies have not been clinically effective due to a number of obstacles. Only a limited number of shared tumor-associated antigens have been identified; epitopes for cellular immunity have not been adequately defined; and few tumor antigens are unique. Tumors commonly lose their distinctive antigen expression and may undergo mutation. In general, vaccine trials are performed with patients with advanced disease. However, in these situations clinical response is difficult to evaluate and statistically uninformative. In addition, inherent systemic immunosuppression in women with advanced disease may prevent an adequate immune response.

In contrast, prophylactic vaccines, such as the recent emergence of the HPV vaccine, have shown great promise for preventing cervical cancer (Harper, 2004; Villa, 2005). These vaccines work by eliciting humoral immune responses to induce the production of antibodies capable of neutralizing a virus before infection (see Chap. 29, Prophylactic Vaccines).

SIDE EFFECTS

Chemotherapy regimens are universally toxic and display a narrow margin of safety. Several agents are associated with classic toxicities that can often be anticipated, and thereby avoided. Because of their limited therapeutic ranges, most agents require dosage adjustment in accordance with individual patient tolerances. Initial chemotherapy dosing is calculated from BSA, weight, renal function, and hepatic function, using specified guidelines from clinical trials. However, numerous other factors influence toxicity and include the patient's baseline nutrition, overall health, extent of disease, and prior therapy. The Cancer Therapy Evaluation Program (CTEP) of the National Cancer Institute (NCI) has developed a detailed and comprehensive set of guidelines for the description and grading of toxicity in collaboration with the Food and Drug Administration (FDA), national cooperative groups, and the pharmaceutical industry (current version: http://ctep.info.nih.gov).

In general, treatment modifications depend on the degree (grade) and duration of toxicity experienced during the preceding therapy course. Doses should be reduced if a woman experiences a severe reaction, but then may be subsequently increased if tolerance improves. However, treatment should not resume until toxicity has resolved to baseline or "grade 1" levels and may be delayed on a week-to-week basis to allow for recovery. Dose modification and supportive care should be implemented to prevent delays of greater than 2 weeks, which would otherwise compromise the therapy efficacy. Serious myelosuppression can be partially corrected with the use of hematopoietic growth factors (Growth Factors). Many of the common toxicities can be prevented with proper use of premedications or alleviated with supportive measures.

Bone Marrow Toxicity

Myelosuppression, especially neutropenia, is the most common dose-limiting side effect of cytotoxic drugs. The absolute neutrophil count (ANC) is most important when determining the risk of infection. The ANC may reflect mild (1,000 to 1,500/mm^3), moderate (500 to 1,000/mm^3) or severe (<500/mm^3) neutropenia. In addition, moderate degrees of anemia are common in cancer patients receiving chemotherapy, which may contribute to chronic fatigue. Frequent transfusions are not practical or recommended, and many patients will adapt to chronic anemia with minimal symptoms. Thrombocytopenia is less common, but may predispose the patient to serious bleeding if a platelet count is <10,000/mm^3 .

Gastrointestinal Toxicity

Most anticancer agents are associated with some degree of nausea, vomiting, and anorexia. Typically, the emetogenic potential of a particular drug or regimen will dictate the anti-emetic regimen used (Tables 27-10 and 27-11). Mild nausea and vomiting can often be managed effectively by prochlorperazine with or without dexamethasone (see Table 39-13). For drugs with more severe emetogenic effects such as cisplatin, the 5-hydroxytryptamine antagonists can be given IV before chemotherapy. The group includes ondansetron, granisetron, and palonosetron. Ondansetron and granisetron may also be provided orally to manage delayed and/or chronic nausea after chemotherapy. Diarrhea, oral mucositis, esophagitis, and gastroenteritis are treated with supportive care.

Table 27-10 Emetic Risk of Intravenously Administered Antineoplastic Agents

Emetic Risk (incidence of emesis without antiemetics)	**Agent**
High (>90%)	Cisplatin Cyclophosphamide ≧ 1,500 mg/m^2 Dactinomycin
Moderate (30â€“90%)	Carboplatin Ifosfamide Cyclophosphamide <1,500 mg/m^2 Doxorubicin
Low (10â€“30%)	Paclitaxel Docetaxel Topotecan Etoposide Methotrexate Gemcitabine
Minimal (<10%)	Bevacizumab Bleomycin

	Vinblastine Vincristine Vinorelbine

Adapted from Kris, 2006, with permission.

Table 27-11 Drug Regimens for the Prevention of Chemotherapy-Induced Emesis by Emetic Risk Category	
Emetic Risk Category (incidence of emesis without antiemetics)	**Antiemetic Regimens and Schedules**
High (>90%)	5-HT_3 serotonin receptor antagonist: day 1 Dexamethasone: days 1â€“3 Granisetron: days 1â€“3
Moderate (30% to 90%)	5-HT_3 serotonin receptor antagonist: day 1 Dexamethasone: days 1â€“3
Low (10% to 30%)	5-HT_3 serotonin receptor antagonist: day 1 Dexamethasone: days 1â€“3
Minimal (<10%)	Prescribe as needed

5-HT_3 = 5-hydroxytryptamine-3.

Modified from Kris, 2006, with permission.

Dermatologic Toxicity

Most drugs can cause a spectrum of toxicity to the skin or subcutaneous tissues, including hyperpigmentation, photosensitivity, nail abnormalities, rashes, urticaria, or erythema. Many of these are drug-specific and self-limited, but occasionally they may be dose-limiting. As discussed earlier, PPE is a known toxicity of liposomal doxorubicin (Prescribing Information and Toxicity). In addition, changes in skin pigmentation are seen with bleomycin, whereas nail discoloration and oncholysis have been associated with docetaxel therapy. Premedication with diphenhydramine hydrochloride will prevent or alleviate mild urticarial reactions.

Neurotoxicity

Peripheral neuropathy occurs commonly with cisplatin, paclitaxel, vinca alkaloids, and hexamethylmelamine. Cisplatin-induced neurotoxicity usually resolves slowly, due to axonal demyelination and loss. This toxicity is related to cumulative dose and intensity, and to counter this toxicity, amifostine (Ethyol, MedImmune, Gaithersburg, MD) may be administered. Amifostine is a prodrug that is dephosphorylated by alkaline phosphatase in tissues to a pharmacologically active free thiol metabolite. This metabolite is believed to reduce cisplatin cumulative toxicity. Although amifostine has been reported to reduce the frequency and severity of platinum-mediated neuropathy, substitution of carboplatin will avoid much of the toxicity.

With chemotherapeutic agents in general, drug dosing may need to be adjusted if peripheral neuropathy becomes problematic, for example, if a patient can no longer hold a cup of coffee. More dramatic instances of acute cerebellar syndromes, cranial nerve palsies or paralysis, and occasionally acute and chronic encephalopathies should be managed with supportive care, and usually discontinuation of the offending agent.

Alopecia

One of the most emotionally distressing side effects of many chemotherapeutic agents is scalp alopecia. Fortunately, this is usually

reversible. With some drugs such as paclitaxel, women will also experience loss of eyelashes, eyebrows, and other body hair. In general, techniques to minimize alopecia are unsuccessful. Instead, women should be counseled regarding cosmetic options such as false eyelashes and wigs.

GROWTH FACTORS

The routine incorporation of hematopoietic drug factors into the administration of chemotherapy produces dramatic results. These commonly used agents are usually given by subcutaneous injection. Of these, epoetin alfa and darbepoetin alfa stimulate red blood cell (RBC) production, prevent the need for frequent blood transfusion, and combat therapy-related fatigue. Alternatively, filgrastim and pegfilgrastim increase granulocyte production, and thereby allow women to continue their treatment schedule without dose delays due to moderate or severe neutropenia.

Epoetin Alfa

This hematopoietic drug is a recombinant glycoprotein that has the same biologic effects as endogenous erythropoietin. As such, it stimulates division and differentiation of RBCs within the bone marrow and is indicated in the treatment of chemotherapy-induced anemia. Epoetin alfa (Procrit, Ortho Biotech, Raritan, NJ, and Epogen, Amgen, Thousand Oaks, CA) is usually prescribed as 40,000 units SC, given weekly (Case, 2006). Beyond local pain at the injection site, this agent has minimal side effects. Possible toxicity may include diarrhea, nausea, or hypertension.

Darbepoetin Alfa

This hematopoietic drug is closely related to epoetin alfa and has the same biologic effects as endogenous erythropoietin. Indicated for the treatment of chemotherapy-induced anemia, the usual SC dose of darbepoetin alfa (Aranesp, Amgen) is 200 μg every other week or 500 μg given every 3 weeks. Darbepoetin alfa has minimal side effects beyond local pain at the injection site. However, use should be discontinued if hemoglobin levels exceed 12 mg/dL to avoid thromboembolic events or other cardiovascular morbidity.

Filgrastim

This protein is a human granulocyte colony-stimulating factor (G-CSF), produced by recombinant DNA technology. As such, filgrastim (Neupogen, Amgen) is a pleiotropic cytokine that binds to hematopoietic cells and activates the proliferation, differentiation, and activation of granulocyte progenitor cells. This agent is indicated as an adjunct to chemotherapy. It allows women to continue their chemotherapy schedule without dose delays from myelosuppression and/or speeds resolution of neutropenic fever episodes.

The usual SC dose of filgrastim is 5 μg/kg/d, but typically patients are given either 300 μg or 480 μg, which is the content of manufactured vials. It must be administered at least 24 hours after the completion of chemotherapy. Therapy should be terminated if white blood counts exceed 10,000/mm^3 or if absolute neutrophil counts exceed 1,000/mm^3 for 3 consecutive days. Toxicity with filgrastim is limited, and transient bone pain is usually mild to moderate.

Pegfilgrastim

This agent acts similarly to filgrastim to stimulate production of granulocyte progenitor cells within the bone marrow. The "peg" in pegfilgrastim (Neulasta, Amgen) refers to a polyethylene glycol unit that prolongs the length of time it remains in the body. Pegfilgrastim is given as a single 6-mg SC injection once per chemotherapy cycle. This is usually far more convenient than daily doses. It should not be administered during the period 14 days before and 24 hours after administration of cytotoxic chemotherapy. Transient bone pain is usually mild to moderate, but often more pronounced than that seen with filgrastim.

CANCER DRUG DEVELOPMENT

The only proven way to improve the success of cancer treatment involves testing new agents, higher doses, novel combinations of drugs, or unique ways of administering treatment. Over the past few decades, clinical trial designs have become increasingly sophisticated and therefore more reproducible. Since gynecologic cancers are relatively uncommon, most landmark phase III studies are conducted within large collaborative groups such as the Gynecologic Oncology Group (GOG). Occasionally, there are astonishing successes. For example, metastatic gestational choriocarcinoma has gone from a uniformly fatal diagnosis to being routinely cured with combination chemotherapy. More commonly, there is a gradual improvement in extending the length of survival that takes years to realize.

The identification of a new and active anticancer drug is a long, complicated, expensive process. Promising drugs are first identified by demonstrating success in cancer cell lines or in animals inoculated with tumor. Next, drugs are subjected to detailed preclinical toxicology tests in animals. After preclinical steps are completed, novel agents proceed through four phases of clinical testing.

Phase I trials use a dose-escalating design to determine the dose-limiting toxicity, maximally tolerated dose (MTD), and pharmacokinetic parameters of the drug. Groups of three to six patients with a variety of tumor types are enrolled at each dose, depending on the amount of toxicity that can be tolerated. In a phase I trial, detecting a tumor response is not critical, since enrolled patients have typically completed extensive prior therapy. However, observed responses would encourage further disease-specific phase II trials.

After the recommended dose and treatment schedule have been defined in a phase I trial, the regimen can proceed to phase II. The primary goal of this trial type is to define the actual response rate in patients with a specific cancer type. Usually a measure of disease (MOD) is required to allow accurate determination of a complete response, partial response, stable disease, or progression. Typically, patients enrolled in phase II trials have received only one prior chemotherapy regimen. This allows for a reasonable chance of response, compared with subjects in phase I studies. Secondary end points of phase II trials include determination of the "progression-free interval", cumulative incidence of dose-limiting toxicity over multiple cycles, and overall survival.

When a promising regimen is identified in phase II, it may then progress to phase III. These randomized trials are designed to directly compare the investigational drug with existing standard regimens in a particular stage and type of cancer. Phase III trials generally require a minimum of 150 patients per arm to provide adequate statistical precision.

In general, patients should be strongly encouraged to participate in appropriate phase I, II, and III clinical trials. By doing so, their options for treatment are expanded. In addition, the results of such studies are the primary method to improve the outcomes of those women diagnosed with gynecologic cancer in the future.

PRINCIPLES OF RADIATION THERAPY: INTRODUCTION

Following the discovery of x-rays in the waning years of the 19th century, the biologic effects of ionizing radiation (IR) were quickly recognized. Since then, radiation therapy (RT) has been used, either alone or in conjunction with other modalities, to treat a variety of conditions, both malignant and benign. Over the last few decades, technological innovation in medical imaging equipment and computers has helped tremendously in RT planning and delivery.

Radiation therapy can be delivered by external beam therapy; internal placement of radionuclide sources, termed *brachytherapy* ; or by instillation of radionuclide solutions. These forms play significant roles in the treatment of various gynecologic malignancies (Table 28-1). For example, external beam therapy and brachytherapy play major roles in the primary management of inoperable cancers of the cervix, vagina, and vulva. Additionally, they may be recommended as adjuvant treatment in the postoperative setting if there is a high probability of regional recurrence. For uterine malignancies, external beam therapy or brachytherapy may be recommended for adjuvant posthysterectomy treatment, or occasionally can be used as a primary modality for inoperable tumors. For epithelial ovary cancer, the indications for RT are minimal. Similarly, there currently is a limited role for external beam therapy in the management of ovarian germ cell tumors and gestational trophoblastic neoplasia (Soper, 2003). Radiation therapy is used frequently in the relief of symptoms caused by metastasis of any gynecologic cancer. Pain, bleeding, spinal cord compression, bronchial obstruction, and brain metastasis can be effectively palliated.

Table 28-1 Role of Radiation Therapy in the Management of Gynecologic Cancers

Intent	Site
Curative	Cervix, vulva, vagina
Adjunctive to surgery	Cervix, vulva, vagina, uterus
Palliative	Metastasis causing symptoms: bleeding, pain, obstruction

RADIATION PHYSICS

Electromagnetic Radiation

Photons and gamma rays are the two most common types of electromagnetic radiation used in RT. Both can be considered as *electromagnetic waves* or as discrete particles (quanta) of energy. This duality is described by the wave-particle theory of quantum physics, which explains that energy can be transferred either by waves or particles. The main distinction between photons and gamma rays lies in their origin. *Photons,* also known as *x-rays,* are produced when a stream of electrons collides with a high-atomic-number target like tungsten. Photons are used in external beam therapy and are produced by linear accelerators, which are described later. In contrast, gamma rays originate from unstable atom nuclei and are emitted during decay of radioactive materials.

Particle Radiation

Whereas electromagnetic waves are defined by their wavelengths, radiation particles are defined by their masses. For clinical use, they include electrons, neutrons, protons, helium ions, heavy charged ions (e.g., carbon, neon, and argon), and pi mesons. Except for electrons, which are in daily clinical use, only a few institutions in the world have the capability to investigate the other particles for cancer therapy. All of these particles are produced by linear accelerators or other high-energy generators designed for physics

research.

Particle radiation is usually delivered by external beam and each particle type has specific biologic and physical properties. *Electrons* are negatively charged and due to their superficial depth-dose characteristics are only suitable for the treatment of cancer near the skin surface, such as inguinal lymph nodes.

Neutrons carry no electrical charge, and therefore transfer energy by nuclear disintegration or by colliding directly with a hydrogen nucleus. Since a high content of hydrogen is found in fat tissues, the energy deposition into fat with this form of radiation is higher than in muscles. This explains the high incidence of fat loss and subcutaneous fibrosis associated with pelvic neutron therapy. Neutron beam therapy is particularly effective for slow-growing tumors and has been used in the treatment of salivary glands, sarcoma, and prostate cancers.

Protons and *helium ions* characteristically deposit the highest energy dose near the maximum depth of beam penetration, with a sharp dose taper after that peak. They are used in the treatment of rare tumors such as uveal melanoma, chordoma, and chondrosarcoma. Finally, h*eavy charged ions* and *pi mesons* are being investigated for the treatment of a variety of tumors.

Radionuclides

Radionuclides, also called radioisotopes, undergo nuclear decay and can emit: (1) positively charged alpha particles, (2) negatively charged beta particles (electrons), and (3) electromagnetic gamma rays. Radionuclides commonly used in gynecologic oncology are commercially available as sealed sources such as cobalt, cesium, iridium, gold, and iodine, or as unsealed solutions of strontium, iodine, or phosphorus (Table 28-2).

Table 28-2 Physical Properties and Clinical Use of Selected Radionuclides

Element	Radiation Energy in MeV	Half-Life	Clinical Use
Cesium-137	0.6	30 years	Brachytherapy
Iridium-192	0.4	74 days	Brachytherapy
Cobalt-60	1.2	5 years	Brachytherapy
Iodine-125	0.028	60 days	Brachytherapy
Phosphorus-32	1.7	14 days	Intraperitoneal instillation
Gold-196	0.4	2.7 days	Intraperitoneal instillation
Strontium-89	1.4	51 days	Diffuse bone metastasis

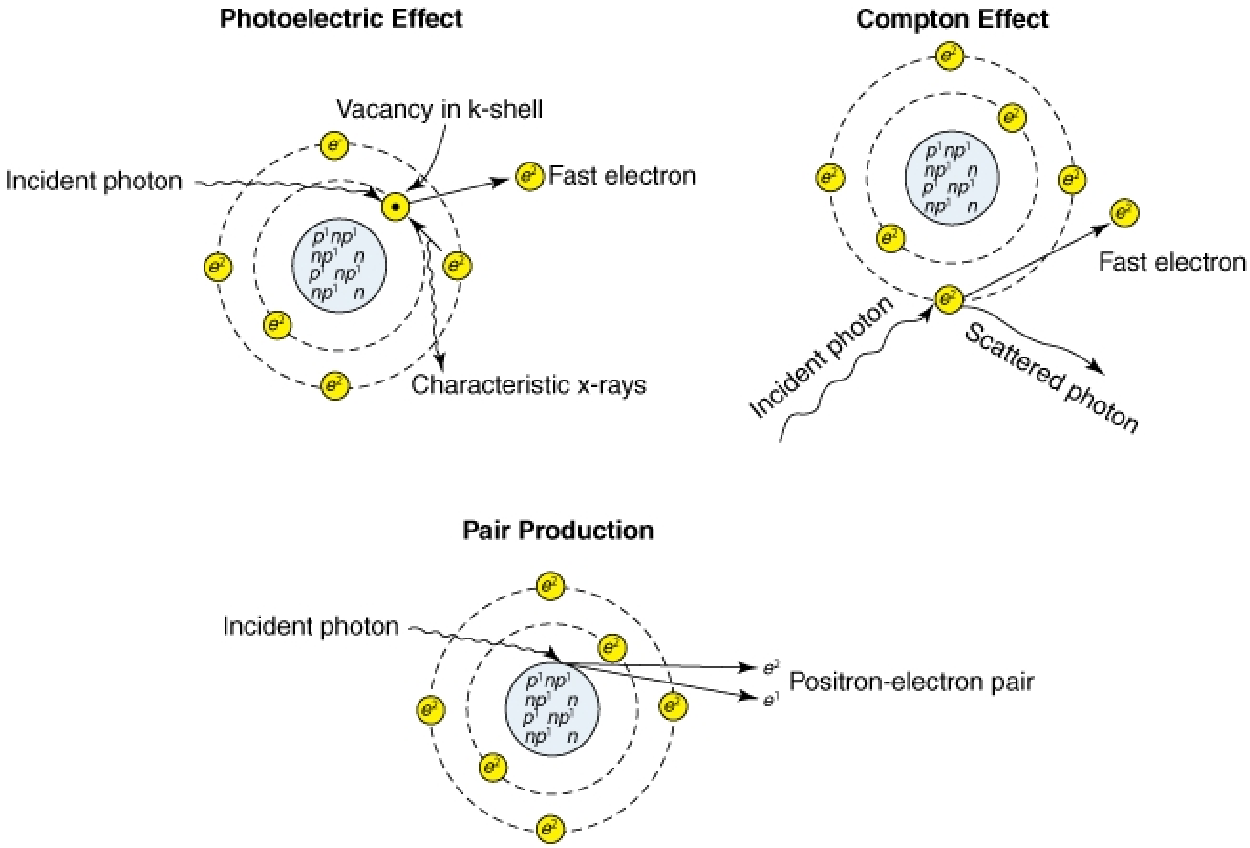
MeV = million electron volts.

Electromagnetic Radiation Energy Deposition

When electromagnetic radiation is used in daily clinical practice, it interacts with tissues, and energy is transferred to those tissues. Importantly, the impacting energy, also called *incident energy* , causes the formation of ions by dislodging electrons from atoms within these tissues. During this ionizing process, energy is transferred to fast electrons, which then interact with the surrounding molecules to initiate the biologic process of radiation damage.

There are three mechanisms involved in the energy transfer: *photoelectric effect, Compton effect,* and *pair production (PP)* (Fig. 28-1). The *photoelectric effect* is dominant when the incident energy is low. The effect causes ejection of an orbiting electron from its shell, and this ejected "fast"-electron kinetic energy is deposited into tissues. After ejection, this vacancy is filled by an electron from an outer orbiting shell with the emission of a characteristic x-ray, which has little biologic effect. The photoelectric effect is proportional to the third power of the atomic number (Z) of the absorbing medium and is inversely related to incident energy.

FIGURE 28-1



Both photoelectric and Compton effects result in the creation of fast electrons which initiate the biologic process of radiation damage. The pair production process involves the interaction of incident photon and nuclear forces to produce a positron-electron pair. When a positron combines with a free electron in tissues, two photons are created. *(Redrawn from Hall, 2003, with permission.)*

Radiologists take advantage of the photoelectric effect in the creation of radiographs. For example, when a pelvic radiograph is obtained for diagnostic purposes, a low x-ray energy is used. Because bones have a higher Z number than muscles and fat, they absorb more energy and appear brighter on radiographs. As a result, bony structures are clearly seen, whereas the muscle and fat tissues are barely identified. In contrast, when a verification pelvic film is taken during a radiation therapy course that uses a high-energy photon beam, the contrast between the bones and soft tissues is less evident.

The *Compton effect* is seen with high-energy photons used clinically in RT. It occurs when the incident photon energy is much larger than the binding electron energy with which the photon interacts. In this interaction, part of the photon energy is transferred to the electron, which is ejected from the orbiting shell. This "fast" electron initiates the biological chain of events leading to DNA damage.

Pair production occurs when a photon beam with very high energy interacts with the electromagnetic field of the nucleus. The result is formation of a *pair* comprised of a negatively charged electron and a positively charged positron. When the positron slows and interacts with a negatively charged electron, there is mutual annihilation, and two photons going in opposite directions are produced. These photons interact with the tissues to transfer energy and cause biologic damage.

Depth-Dose Curve

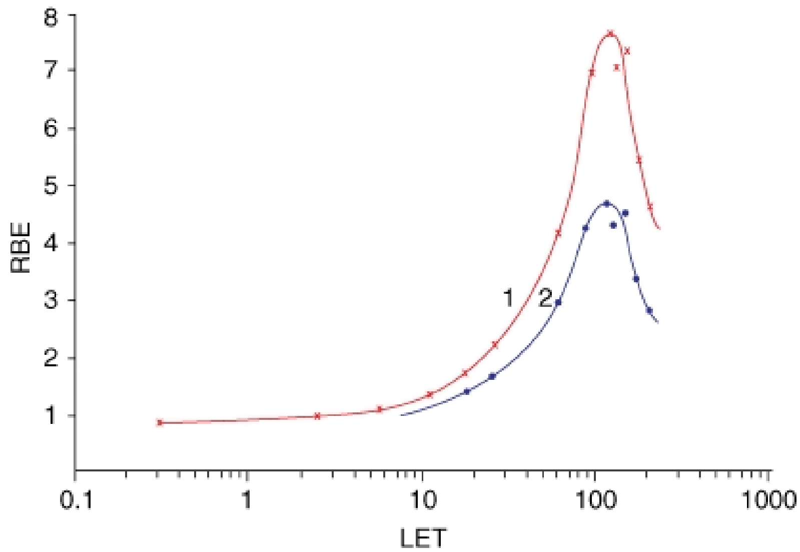
With high-energy photons, maximum energy is deposited below the tissue surface, and beyond this point, the dose gradually tapers

as the energy is absorbed by the deep surrounding tissues. This explains the so called *skin-sparing effect* of high-energy photons. In contrast, with electron beam therapy, the maximum dose lies much closer to the surface and the dose distribution has a steeper taper. For this reason electron beam therapy is preferred for targets which are close to the skin surface such as disease metastatic to the inguinal lymph nodes.

Linear Energy Transfer and Relative Biologic Effectiveness

When a radiation beam interacts with tissue, ionizing events occur along the path of energy transfer. The rate of energy deposition along this path is called *linear energy transfer* or LET, which is expressed as kiloelectron volts (keV) per micrometer. Photons, gamma rays, x-rays, electrons, protons, and helium ions are classified as low-LET radiation since the ionizing events tend to be sparse. In contrast, high-LET radiation, such as heavy particles (fast neutrons, heavy charged ions, and pi mesons), creates dense clusters of ionization and as a result, are more biologically damaging. To compare the biologic effectiveness of different radiation types, a parameter called *relative biologic effectiveness* (RBE) is used. It is defined as the ratio of photon to neutron doses used to achieve a specified biologic end point. Therefore, it should be noted that RBE values depend on the chosen biologic end points under consideration. As the LET increases, RBE also increases and reaches a peak at 100 keV/micron (Fig. 28-2).

FIGURE 28-2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Linear energy transfer (LET) as a function of relative biologic effectiveness (RBE). RBE reaches its maximum at about 100 keV/micron and varies depending on biologic endpoints. Curves 1 and 2 refer to cell survival of 80 percent and 10 percent, respectively. *(Adapted from Barendsen, 1968, with permission.)*

Radiation Unit

The biologic effect of ionizing radiation (IR) correlates well with the amount of energy transferred to tissues. Therefore, in the practice of radiation oncology, quantification of the absorbed radiation dose delivered to tissues is essential. In older terminology the unit of measure, called *rad* , was used to describe the absorbed dose. One rad, literally *radiation absorbed dose* , is defined as 100 erg/g. Currently, the Standard International unit for an absorbed dose is gray (Gy). One Gy equals 100 rad or 1 joule/kg. Clinically, the radiation doses for curative and palliative treatments are 70 to 85 Gy and 30 to 40 Gy, respectively.

Radiation Equipment

LINEAR ACCELERATOR (LINAC)

As technology has advanced, the armamentarium for deep radiation delivery has vastly expanded from the kilovoltage to

megavoltage unit. Among the many types of photon-producing megavoltage units, the linear accelerator, also called a *linac* , is the one that is widely used throughout the world to deliver external beam radiation therapy.

A linac can produce both photon and electron beams for therapeutic use (Fig. 28-3). The electrons are produced by an electron gun and are injected into a linear tube where they are accelerated by electromagnetic waves produced by a klystron. A modulator then synchronizes the pulsed injections of electrons and electromagnetic waves into the accelerator tube. In the *photon-therapy mode* , indicated for deep-seated tumors, the accelerated electron beam is guided to a metal target via a beam steering system producing photons with heterogeneous energies. Before clinical use, this beam hits a flattening filter to make its intensity uniform (Fig. 28-4). In contrast, in the *electron-therapy mode* for superficial lesions, the electron beam strikes a scattering foil instead of the metal target.

FIGURE 28-3

To create radiation beams with uniform dose distribution across the treatment fields, linear accelerators modify beams with filters and foils. In the photon therapy mode **(A),** the electron beam strikes a flattening filter. In the electron therapy mode **(B),** it hits a scattering foil. *(Redrawn from Karzmark, 1981, with permission.)*

The unit used to describe the energy of a photon beam is MV (million volts). The unit for electron beam energy is expressed in MeV (million electron volts). Customarily, a linac is designated by a number corresponding to the highest energy of the electron beam available. For example, the maximum energy of the electron beam produced by a linac 18 is 18 MeV.

Figure 28-5 displays a linac with four components: stand, gantry, treatment head, and couch (Varian Inc., Palo Alto, CA). The power source, modulator, and klystron are located in the stand. The electron gun, accelerator tube, and bending magnets are housed in the gantry. The treatment head is mounted on the gantry and contains the metal target, flattening filter, scattering foil, and collimators, which shape the treatment fields (see Fig. 28-4). The gantry, treatment head, and treatment couch can all rotate 360 degrees. Thus, the mobility of the basic components of the linac allows the use of multiple fields and angles to achieve optimal dose delivery to the tumor while minimizing the exposure of normal tissues.

The gantry (G), couch (C), and head (H) can all rotate and allow radiation beams to reach the targets through different angles. (*Courtesy of Dr. Geoffrey Zhang.*)

COBALT MACHINE

Although linacs are widely installed for cancer treatment around the world, cobalt machines are still being used for external beam therapy in a very few centers in the U.S. and in most developing countries. The unstable radioactive cobalt-60 isotope undergoes nuclear decay by emitting 1.17 MV and 1.33 MV gamma rays. However, this isotope's half-life is short (5.2 years), and thus the source requires frequent replacement, every 4 to 5 years.

RADIATION BIOLOGY

Direct versus Indirect Effects of Ionizing Radiation

About 70 percent of the ionizing effects of low-LET electromagnetic radiation, such as photons used in clinical settings, are *indirect.* Energy is transferred from the radiation to the target through chemical intermediates. Tissues are mostly formed of water. The interaction between electromagnetic radiation and water molecules produces the H_2O^+ ion, which then reacts with water to form a free radical, the hydroxyl radical ($OH^{\text{â€“}}$). Because of this radical's unpaired electron, it is highly reactive and easily transfers energy to the target tissue. It is this interaction between hydroxyl radicals and DNA molecules that leads to biologic damage. However, for the chemical changes within the DNA to be permanent or "fixed", free radicals must interact with oxygen. Without the presence of oxygen, this reaction cannot occur. This is the basis for the so called "oxygen fixation" hypothesis. Ninety-five percent of the energy deposited by electromagnetic radiation in tissues occurs within 4 nm of the ionization track, that is, about two DNA molecule diameters.

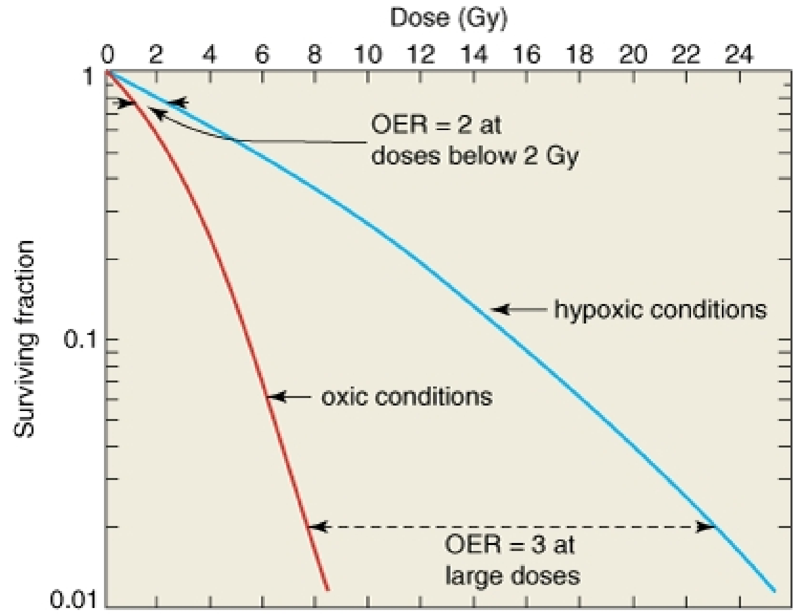
In contrast, particle radiation (protons, neutrons, electrons, and heavy ions) produces ionizing events by *direct* collision with their

biologic targets.

Importance of Oxygen

As noted above, the presence of oxygen is critical to the response of mammalian cells to low-LET radiation. The oxygen enhancing ratio (OER) is the ratio of doses needed to achieve the same cell survival fraction in hypoxic and oxic environments. The OER value depends on the type of IR. For low-LET photons, the OER is approximately 3. This means that the dose needed to achieve a defined biologic effect on a population of hypoxic cells is 3 times higher than the one used to have the same results in oxic conditions. In contrast, for high-LET heavy particles like neutrons, the OER is about 1.5. This implies that tumor hypoxia becomes less relevant with high-LET, and therefore high-RBE radiation (Fig. 28-6).

FIGURE 28-6



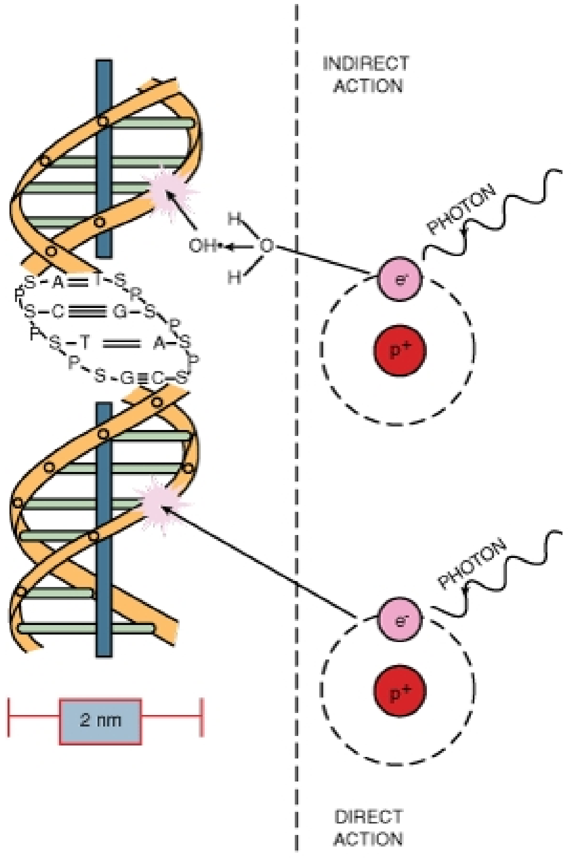
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Cells in an oxic environment are sensitive to radiation, that is, their surviving fraction is decreased, compared with that in hypoxic conditions. The oxygen enhancing ratio (OER) is the ratio of doses needed to achieve the same surviving fraction in hypoxic and oxic conditions. *(Redrawn from Hall, 2003, with permission.)*

DNA Molecule as Ionizing Radiation's Target

There is strong evidence to indicate that the target for the biologic effect of IR on mammalian cells is the DNA molecule (Fig. 28-7). DNA injuries involve the strands, bases, and cross-links (DNA-DNA and DNA-protein). The hallmark of intracellular radiation damage is the breaking of the DNA molecule strands. Single- (SSB) and double-strand breaks (DSB) may occur. Single-strand breaks develop when only one strand is damaged and are easily repaired. Currently, radiation biologists agree that the most important lesion is the DSB. Double-strand breaks effectively create DNA fragmentation when two or more breaks are formed in opposite locations of the DNA ladder. When cells attempt to repair the strand breaks, the DNA pieces may rejoin incorrectly leading to gene translocation, mutation, or amplification. Cell death can follow, and increasing numbers of DSBs have been positively correlated with cell death.

FIGURE 28-7



Direct and indirect actions of radiation. In direct action, an electron that results from absorption of a photon interacts with DNA. With indirect action, an electron produced from photon absorption interacts with water to create a hydroxyl radical, which subsequently interacts with DNA. A, T, G, C = base nucleotides; P = phosphorus; S = sugar. *(Redrawn from Hall, 2000, with permission.)*

Cell Death

After ionizing radiation (IR) exposure, cells sustain damages triggering competing death and survival signals. How cells deal with that stress will determine their ultimate fate. A cell is considered biologically dead when it has lost its reproductive capacity. The two main cell death pathways are apoptosis and mitotic death.

APOPTOSIS

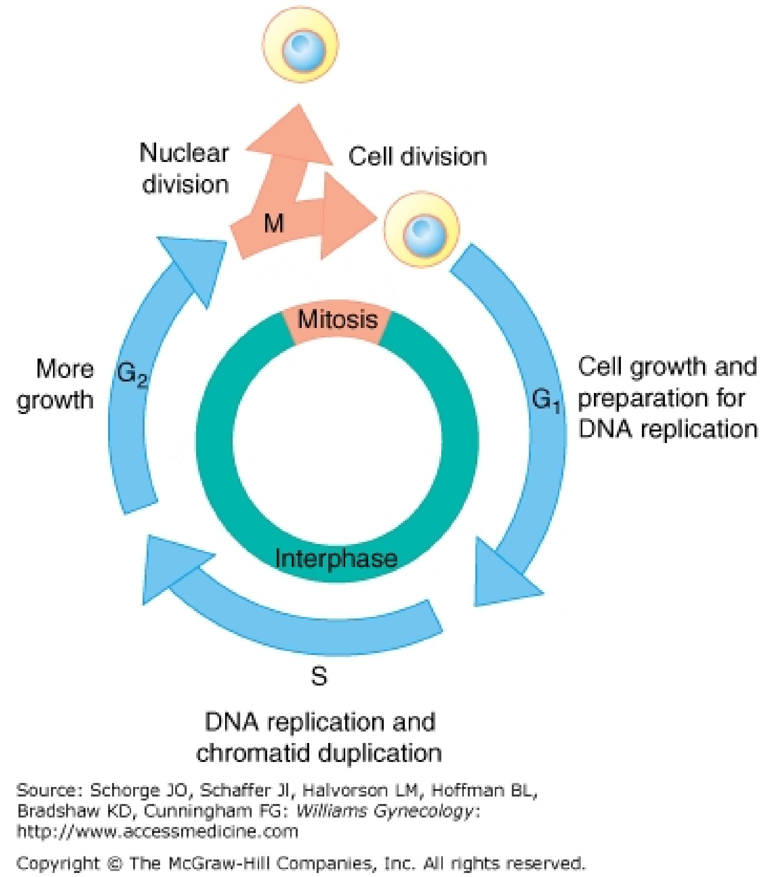
Apoptosis, derived from a Greek word which means *dropping of leaves from a tree* , is also known as programmed cell death or interphase death. It occurs naturally in normal organisms to limit cell proliferation and maintain homeostasis. Dysregulation of the normal apoptotic process is believed to play a role in carcinogenesis as well as numerous other pathologic conditions.

After an intracellular stress, such as IR-induced irreparable DSB, a series of events develop rapidly within a few hours and cell membrane blebbing, formation of apoptotic bodies in the cytoplasm, chromatin condensation, nuclear fragmentation, and DNA laddering can be seen (Okada, 2004). Apoptotic tendency is seen in lymphocytes, spermatogonia, salivary glands, and some tumors that are responsive to IR. Such tissues are believed to have a "pro-apoptotic phenotype". Conversely, cells with "anti-apoptotic phenotype" are resistant to IR. The clinical significance of IR-induced apoptosis resides in the assumption that the factors that shape the death pathways determine the intrinsic cellular radiation sensitivity.

MITOTIC DEATH

A cell cycle has four phases: G_1 , S, G_2 , and M (Fig. 28-8). Cells with damaged DNA are frequently blocked at the G_2 /M checkpoint from moving along the cell cycle to the mitotic (M) phase. If these cells enter the M phase prematurely, before DNA repair is complete and with aberrant chromosomes, they will form multinucleated giant cells with uncondensed chromosomes and will die attempting to complete the next two to three mitotic cycles. Therefore, a mitotic death is delayed in contrast with the more immediate apoptotic death.

FIGURE 28-8



Mammalian cell cycle. DNA replicates in the S phase, whereas in the M phase, the cell divides.

Cells, such as those in ataxia telangiectasia, have defective G_1 /S and G_2 /M checkpoints, allowing cells with damaged DNA to move along the cell cycle. As a result, they are exquisitely sensitive to IR. Human papillomavirusâ€"positive cervical cancer cells with oncoproteins E6 and E7 have also been found to have a defective G_1 /S checkpoint and are capable of developing genomic instability and apoptosis. Moreover, exposed to neocarzinostatin, an agent which causes SSBs and DSBs in DNA, cervical cancer cells demonstrate a strong G_2 /M arrest and a higher percentage of mitotic death when compared with normal human keratinocytes (Banuelos, 2003).

Cell Repair

After IR exposure, cells which survive will repair their damage. Two types of repair have been described: sublethal damage repair (SLDR) and potentially lethal damage repair (PLDR). Currently, the molecular mechanisms of SLDR and PLDR are unknown. Both SLDR and PLDR have been observed in normal and tumor tissues.

SUBLETHAL DAMAGE REPAIR

When a radiation dose is split into two or more fractions and a few hours separate each fraction, cells have time to repair their

damage, and their rate of survival increases. This type of repair is typically completed within 6 hours after IR. During SLDR, a number of characteristic processes have been noted. Following the initial *repair* of sublethal damage, *reassortment* begins. In a tumor, proliferating cells are located at different phases of the cell cycle. When exposed to IR, those cells which happen to be at G_2 /M phase are most sensitive to IR and are killed. During reassortment, surviving cell populations restart their progression through the mitotic cycle. In this manner, all cells within a tumor reassort or redistribute themselves into different phases of the cycle. Following reassortment, mitosis begins again. The last process seen in SLDR is *repopulation* , the tissue response to replenish the cell pool (Trott, 1999).

POTENTIALLY LETHAL DAMAGE REPAIR

After IR exposure, certain environmental conditions, when applied to the irradiated tissues, can lead to increased cell survival. Conditions such as decreased nutrients or lower temperatures, which are suboptimal for growth, allow more time for repair of DNA damage. In these settings, the ability of cells to repair the IR-induced damages correlates with their radiation sensitivities (Kelland, 1988).

The Four R's of Radiation Biology

In addition to cellular repair, reassortment, and repopulation, the fourth "R" of radiation biology theory is a phenomenon called reoxygenation. A tumor cell population is composed of oxygenated and hypoxic components. Those cells that are located within 100 microns of blood capillaries are oxygenated, and those beyond 100 microns are hypoxic. After a dose of IR, the oxygenated cells die because they are radiosensitive. As a consequence, the tumor shrinks, allowing for hypoxic cells to be repositioned within the range of oxygen diffusion from the blood capillaries. Thus, these previously hypoxic cells now become oxygenated and die when another dose of IR is delivered.

Cell Survival Curve

The survival curve of mammalian cells exposed to low-LET IR illustrates the relationship between the IR dose and the proportion of the cell population that retains the ability to proliferate. Among the many models, the one called linear-quadratic has been adopted to explain this relationship. The curve is composed of two parts. The initial linear portion of the curve reflects that the probability of cell death is proportional to the IR dose, whereas the curved quadratic portion indicates that the probability is proportional to the square of the dose. The components of the cell survival curve therefore are expressed as alphaD and betaD^2 . The dose is denoted by "D", but alpha and beta are constants. At the dose D = alpha/beta, there is an equal contribution to cell death from the linear and quadratic parts.

In contrast, when high-LET IR, such as neutron therapy, is used, the shape of the curve is straight.

Clinical Implication of the Alpha:Beta Ratio

Not all normal tissues respond similarly to IR. Those that manifest reactions to IR within a few days to weeks after IR initiation are categorized as *early responding* . Examples are tissues with a high proliferation rate like bone marrow, reproductive organs, and gastrointestinal tract mucosa. Their alpha:beta ratio values are high and are reflected by the steep early slope on the cell survival curve. In contrast, *late responding* tissues only show clinical reactions weeks to months after completion of a course of radiation therapy. It is postulated that late responding tissues are composed of cells in G_0 , the quiescent stage. Examples are the lung, kidney, spinal cord, and brain.

By using multiple small dose fractions, the alpha component is amplified. Thus, with treatment protraction, there is an opportunity to decrease acute reactions. For patients who have IR delivered to the abdomen, in which the mucosal tissues are early responding, treatment protraction is preferred. Alternatively, late responding tissues are slow to respond by proliferative reaction and their alpha:beta ratio values are low. A low ratio value means that the cell survival fraction is markedly decreased when the dose per fraction is high. It takes more time to repair sublethal damage in late-responding than in early-responding tissues. Therefore, the use of high-dose-per-fraction RT can easily lead to severe late complications. Accordingly, there is a high incidence of myelitis if the spinal cord receives a high IR dose in a short period of time, that is, a large fraction dose.

RADIATION THERAPY

External Radiation Therapy

External radiation therapy is indicated when an area to be irradiated is large, for example the fields covering a cervical cancer and the draining nodes. The basic tenet of radiation therapy is to maximize the tumor dose while minimizing the damage to the surrounding normal tissues. To attain this goal, the radiation oncologist must know the precise extent of the cancer to be irradiated and its relationship to the surrounding normal tissues.

This process begins with a review of the patient's cancer imaging. Modern imaging tools include computed tomography (CT), magnetic resonance (MR) imaging, and functional imaging techniques such as nuclear MR imaging/spectroscopy, positron emission tomography (PET) and single-photon emission computed tomography (SPECT). These have aided the radiation oncologist tremendously in defining three-dimensional tumor and healthy tissue volumes (Chapman, 2001; Kwee, 2004, Zakian, 2001).

Following image review, *radiation therapy simulation* is performed to delineate the anticipated therapy fields prior to an actual treatment session. During this process, patient positioning and treatment fields are defined, and radiation blocks are designed to shield normal tissues. Both x-ray machines and CT scanners can be used in simulation. X-ray machine simulators are currently used for simple cases such as palliative planning for metastatic cancer to the brain, bones, and other organs. For most patients, a CT simulation is required using a CT scanner with additional equipment that aids treatment planning.

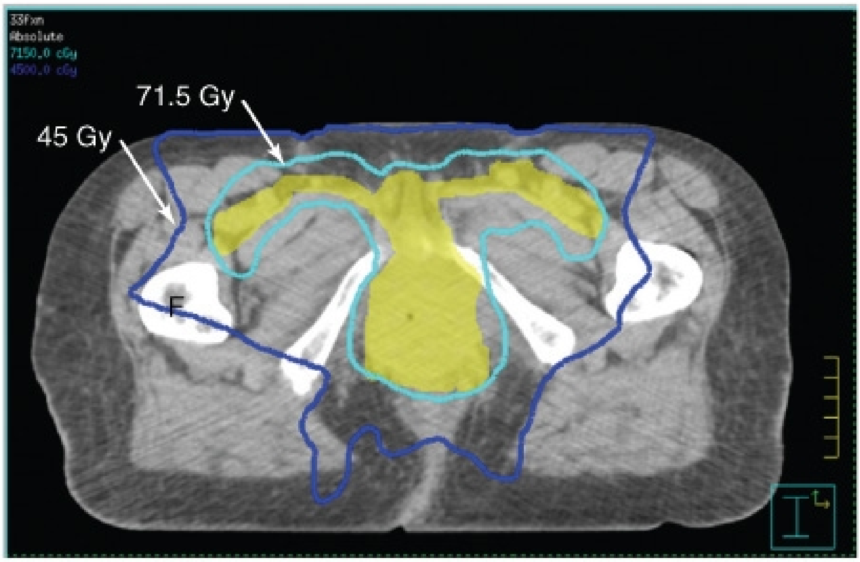
During simulation, the patient is placed in position for treatment, and a CT scan of the area of interest is performed. On each of the CT scan slices, the radiation oncologist delineates by hand the target volumes that are to receive a tumoricidal dose, as well as those at risk for early and late radiation complications. With these specifications, the radiation dosimetrist employs treatment planning software. During this step, the optimal arrangement of the radiation beams, in the case of external radiation therapy, or radioactive sources, in the case of brachytherapy, is developed to achieve treatment goals. This step is called *dose optimization* .

One tool that is particularly helpful in the radiation planning and optimization process is the dose volume histogram. This imaging tool displays the entire dose distribution for the cancer and normal structures. Three-dimensional conformal radiation therapy (3D-CRT) dose distributions are generated for the radiation oncologist to review, adjust, and finally approve. The final chosen plan is checked by a radiation physicist who ensures that the physical and technical details can be implemented.

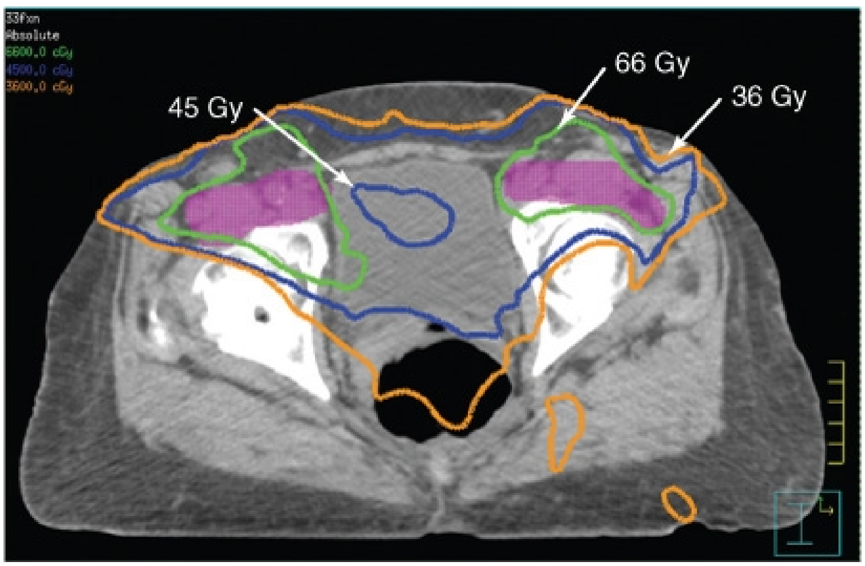
In an effort to further improve the conformality of the dose distribution, especially around concave-shaped targets, a more advanced 3D-CRT planning system, called *intensity-modulated radiation therapy (IMRT)* , is used. As a result of this improved conformality, IMRT has the potential to decrease bowel and bladder toxicity during pelvic IR therapy (Heron, 2003).

In this system, the intensity of the radiation beams is modulated or changed according to the dose constraints or limits assigned to different regions within the irradiated fields (Fig. 28-9). The radiation oncologist defines the dose specifications to different areas. Then, the computer, by a reiteration or trial process, comes up with an optimal solution. This type of treatment planning is called *inverse planning.* In other words, the radiation oncologist first defines the doses to be delivered to tumor and normal tissues. This differs from *forward planning* . For example, in the forward planning for the more common pelvic malignancies, the radiation oncologist chooses an a priori standard pelvic four-field technique.

FIGURE 28-9



A



B

IMRT dose distribution in a patient with stage T4N2M0 cancer of the vulva. This technique allows for the delivery of tumoricidal doses to the vulva and inguinal nodes while minimizing delivery to normal tissues such as rectum, bladder, and bones. **A.** Doses to the vulva and femoral heads are shown **(arrows)** . The yellow area displays the actual vulvar cancer and inguinal lymph nodes. **B.** Doses to vulva, rectum, and femoral heads are shown **(arrows)** . Pink shading displays the inguinal nodes.

For quality assurance purposes, there is weekly or sometimes daily film verification. The radiation oncologist compares the portal

images taken on the treatment machine with the original simulation films. If deviations are noticed, adjustments are made. The radiation oncologist also monitors the patient weekly for untoward treatment side effects. If severe acute complications develop, treatment plans may be revised or a break in treatment may be warranted.

Brachytherapy

Brachytherapy (radiation implant) means treatment at a short distance. During this therapy, sealed or unsealed radioisotopes are inserted or instilled into the cancer or its immediate vicinity. Radiation doses decline sharply with increasing distances from the radioactive source. Accordingly, brachytherapy (BT) is indicated only when the cancer volume is small, less than 3 to 4 cm in greatest dimension. For this reason, BT is typically practiced after external radiation therapy has decreased the tumor size.

INTRACAVITARY, INTERSTITIAL, AND INTRAPERITONEAL BRACHYTHERAPY

During *intracavitary BT* , the applicators holding the sealed sources, such as cesium, are inserted into a body cavity such as the uterus. Alternatively, *interstitial BT* requires the placement of catheters or needles directly into the cancer and surrounding tissues. The typical source used in interstitial BT is iridium. Unsealed sources, such as phosphorus and gold, are available as solutions for instillation into peritoneal cavities.

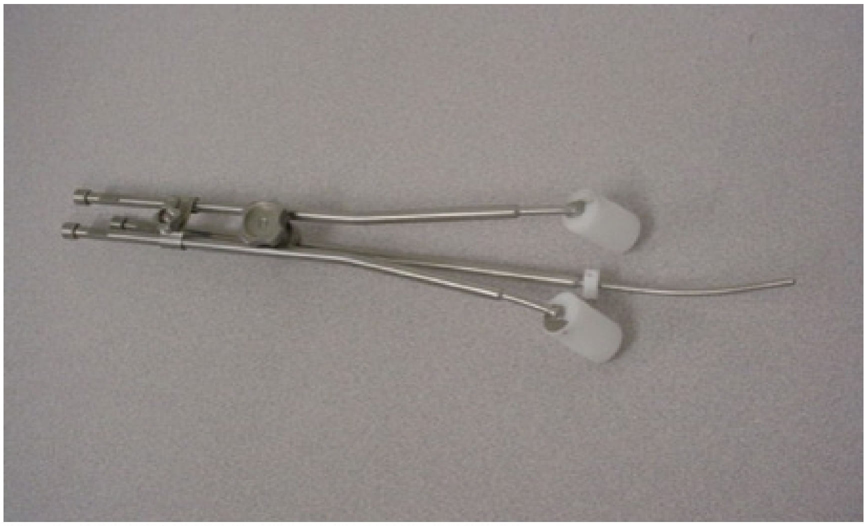
TEMPORARY AND PERMANENT BRACHYTHERAPY

In *temporary BT* , the radioisotopes are removed from the patient after a period of time ranging from minutes to days. All intracavitary and some interstitial implants are temporary. In *permanent BT* , the radioisotopes are left to decay within the tissues. The time for the delivery of the absorbed dose varies depending on the isotopes used and ranges from 1 week with gold to 6 months with iodine.

EQUIPMENT

For routine gynecologic intracavitary implantation, standard equipment includes an applicator, called a *tandem* , which fits into the uterus, and a pair of vaginal applicators, which are known as *ovoids* or alternatively, called *colpostats* (Fig. 28-10). Tandems have different curvatures to adapt to varied uterine shapes. Similarly, plastic caps can be fitted to ovoids to adapt to varied vaginal anatomy. The tandem and ovoid device (T&O) is inserted under general anesthesia or conscious sedation. Following placement, radioactive sources can then be loaded into the tandem and ovoids either manually or remotely. In gynecologic oncology, brachytherapy with T&O is indicated for cancer of the cervix and endometrium.

FIGURE 28-10



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Typical tandem and ovoids (colpostats) used for cervical cancer brachytherapy. The device is inserted into the endometrial cavity and vagina. An iridium radioactive source is loaded into the device via a remote control mechanism. (*Courtesy of Dr. Geoffrey Zhang.*)

In contrast, for temporary interstitial implantation, flexible plastic catheters or metal needles are surgically placed into the target tissues. These are then afterloaded with iridium seeds. To achieve an optimal dose distribution, the catheters or needles should stay firmly in place. For this reason, a perineal template is often used. Although used less frequently than T&O, templates are suitable in the management of patients with advanced cancer, with suboptimal anatomy for T&O application, and with selected recurrent cancer.

MANUAL VERSUS REMOTE AFTERLOADING

During brachytherapy, once the holding devices for the radioactive sources are optimally positioned, the sources are inserted. Previously, these sources were carried in a shielded cart to the patient's room, loaded into the patient, and then removed and replaced in a storage room following treatment. This *manual afterloading* method increased hospital staff radiation exposure. For this reason, a *remote afterloading* approach was developed and is commonly practiced today. This remote control system delivers through connecting cables a single miniaturized iridium or cobalt source to the holding devices previously inserted into the patient. When IR is actually delivered, personnel are outside the patient's treatment room. Following treatment, the radioactive source is automatically retracted back into the safe.

LOW DOSEÂ€“RATE VERSUS HIGH DOSEÂ€“RATE THERAPY

Traditionally, low doseâ€“rate (LDR) brachytherapy is delivered over the course of many days and requires patient hospitalization. Over the last few decades, however, high doseâ€“rate (HDR) brachytherapy has become more popular. With this technique, treatment is shortened to minutes. Low dose rate is defined as dose rates from 0.4 Gy to 2 Gy/hr, and HDR as rates higher than 12 Gy/hr. For example, in an intracavitary implant for cervical cancer with an LDR technique, a dose of 30 to 40 Gy is given over several days continuously. In contrast, in an HDR technique, an equivalent dose can be delivered in 3 to 5 weekly fractions. The dose per fraction is 6 to 8 Gy and can be given in 10 to 20 minutes.

The radiobiology differences between LDR and HDR brachytherapy are based on the dose-rate effect. As the dose rate increases there are: (1) decreased cell survival of tumor and early-responding normal tissues due to the lack of tissue injury repair, and (2) increased damage to the late-responding normal tissues. Therefore, to avoid late complications, the number of fractions is increased from 1 to 2 in LDR to 3 to 6 in HDR brachytherapy. Furthermore, the total tumor dose delivered in HDR brachytherapy of the cervix is lower than the one used in LDR (Nag, 2000). This dose is divided into brief fractions that avoid lengthy inpatient hospitalization and minimizes patient immobility and thromboembolic events. Long-term analysis has not shown any striking differences in local tumor control or in late complications in patients with cervical cancer treated with either HDR or LDR brachytherapy (Arai, 1991; Hareyama, 2002; Wong, 2003).

RADIATION ONCOLOGY PRACTICE

Background of Fractionated Radiation Therapy

STANDARD FRACTIONATION

In the early 20th century, controversy grew concerning two different approaches for radiation therapy delivery in the treatment of human cancers. One school recommended the delivery of a massive radiation dose within a short time interval. The assumption was that a rapidly growing tumor would retain the capacity to recover quickly from radiation damage if a tumoricidal dose was not given in the first treatment session (Thames, 1992). Alternatively, smaller doses given over many days to weeks were advocated by others as a method to minimize radiation side effects.

The controversy was resolved when Coutard (1932), along with the work of others, found success with this type of *fractionated IR* . As a result, in the U.S. since the 1950s, the practice of giving 1.8 to 2 Gy a day, 5 days a week has been considered standard or conventional.

ALTERED FRACTIONATION

In an effort to increase local tumor control as well as decrease long-term complications, fraction size and overall treatment time duration have been manipulated, leading to a variety of altered fractionations. Two major strategies have been employed: hyperfractionation and accelerated treatment. These both differ from the standard therapy in that multiple fractions are given each day.

With hyperfractionation, the reduction of late damage to normal tissues is sought, and accordingly, a smaller dose per fraction is given. Two or more fractions are administered each day.

As noted earlier, there is tumor repopulation during a conventional 6- to 7-week course, which may lead to treatment failure. To counter these problems, an accelerated treatment schedule may be used. This entails shortening the treatment duration with or without a decrease in total dose. The usual weekend break is either shortened or eliminated. With accelerated treatment, however, severe acute reactions are frequently encountered. Often a mandatory rest period in the middle of the treatment course is required (Wang, 1988).

Altered fractionation has been studied in cervical cancer. The tumor control, late toxicity, and survival results were similar to historical rates achieved by standard fractionation (Grigsby, 2002; Komaki, 1994). However, it was poorly tolerated, especially when large-field radiation therapy and chemotherapy or both were added (Grigsby, 1998; Marcial, 1995).

Tumor Control Probability

With most of epithelial cancers, the probability of IR to control a cancerous mass depends on the tumor size and intrinsic radiosensitivity and on the radiation dose and delivery schedule. For example, within a given stage, large tumors are more difficult to control with IR than smaller ones (Bentzen, 1996; Dubben, 1998).

INTRINSIC RADIOSENSITIVITY

Although it is recognized that a tumor's radiosensitivity in general is determined by its pathologic type, even cancers within a similar histology may have variable responses to IR (Table 28-3). In addition, heterogeneity within a given tumor may explain this varied response. Another factor that seems to play a role in determining tumor radiosensitivity is its ability to repair radiation damage. For example, the rate of DNA double-strand break repair was found to correlate well with radiosensitivity of tumors (Schwartz, 1988, 1996; Weichselbaum, 1992).

Table 28-3 Radiosensitivity of Some Selected Cancers

Sensitivity	Cancer Type
Highly sensitive	Lymphoma, dysgerminoma, small cell cancer, embryonal cancer
Moderately sensitive	Squamous carcinoma, adenocarcinoma
Poorly sensitive	Osteosarcoma, glioma, melanoma

TREATMENT TIME

When protracted time intervals are required to complete a fractionated IR course, tumor control probability decreases, especially in rapidly proliferating epithelial cancers. Therefore, treatment breaks or delays for any reason should be minimized. In a retrospective review of 209 patients with stage 1 to 3 cervical cancer treated with IR, the 5-year pelvic control and overall survival rates were better for those who completed the treatment in less than 55 days (87 percent and 65 percent, respectively) than for those who did so in more than 55 days (72 percent and 54 percent, respectively) (Petereit, 1995).

Tumor Hypoxia

With primary radiation therapy, tumor hypoxia is one of the major factors leading to poor local tumor control and poor survival in patients with cervical cancer (Brizel, 1999; Nordsmark, 1996). For example, the close relationship between tumor hypoxia, anemia, and angiogenesis was demonstrated in a study involving 87 patients with stage 2, 3, and 4 cervical cancer treated with IR only. Of these, patients with a hemoglobin level of less than 11 g/dL, a median tumor oxygen tension less than 15 mm Hg, and an

increased tumor microvascular density had decreased 3-year survival (Dunst, 2003). For this reason, many strategies have been devised to overcome tumor hypoxia.

HYPERBARIC OXYGEN

Hyberbaric oxygen used in conjunction with radiation therapy in stage 2 and 3 cervical cancer has not been shown to be effective in clinical studies (Dische, 1999). In addition, there is concern that hyberbaric oxygen may accelerate tumor growth (Bradfield, 1996).

A more convenient method of increasing the delivery of oxygen to tissues involves manipulating blood vessel hemodynamics with either carbogen or nicotinamide. *Carbogen* (95-percent oxygen and 5-percent carbon dioxide) is an oxygen preparation with increased intratumoral diffusion capabilities. When inhaled during concurrent external radiation therapy, carbogen has been shown to increase tumor oxygen pressure and is well tolerated (Aquino-Parsons, 1999). Alternatively, *nicotinamide* is the amide derivative of vitamin B_3 and has been shown to prevent intermittent vascular shutdown. In combination, carbogen and nicotinamide are thought to increase oxygen delivery to diffusion-limited hypoxic regions.

BIOREDUCTIVE AGENTS

This family of hypoxic sensitizers exploits the tumor's hypoxic environment to initiate a series of hypoxia-activated biochemical events. These steps lead to the production of cytotoxic agents that selectively kill hypoxic cells. During the last decades, the agents mitomycin C and tirapazamine, have been proved clinically effective (Craighead, 2000; Nguyen, 1991; Rischin, 2001).

BLOOD TRANSFUSION

In clinical practice, it is desirable to bring the hemoglobin level of patients receiving IR to at least 12 g/dL. It has long been believed that transfusion ameliorates tumor hypoxia and increases IR response. For example, in a review of a group of 204 women with cervical cancer who were treated with IR, 26 percent had a hemoglobin level of <11 g/dL, either before or during the IR course. They received packed red blood cell transfusion. Of these, only 18 percent of the women who received transfusions were able to maintain a hemoglobin level of >11 g/dL throughout the treatment. This subset of women had a similar 5-year disease-free survival rate of 71 percent compared with a group of women who never required transfusion. The disease-free survival rate was only 26 percent for those with persistent anemia. Not all patients, however, showed marked benefit from transfusion, especially those with nodal metastasis, late stage, and large tumor size (Kapp, 2002).

RECOMBINANT HUMAN ERYTHROPOIETIN

In addition to transfusion, recombinant human erythropoietin (EPO) has been used to correct anemia and is discussed in Chapter 27, Growth Factors. Clinically however, this therapy has not proved to be beneficial in those receiving RT. In a Southwest Oncology Group phase II multi-institutional trial, EPO and iron supplements produced an inadequate increase in hemoglobin levels, There was additional concern that EPO increased the risk of deep vein thrombosis (Lavey, 2004; Wun, 2003). Moreover, according to one report, it was more economical to administer blood transfusions than EPO to correct anemia in patients with cervical cancer who were receiving concurrent cisplatin and IR (Kavanagh, 2001).

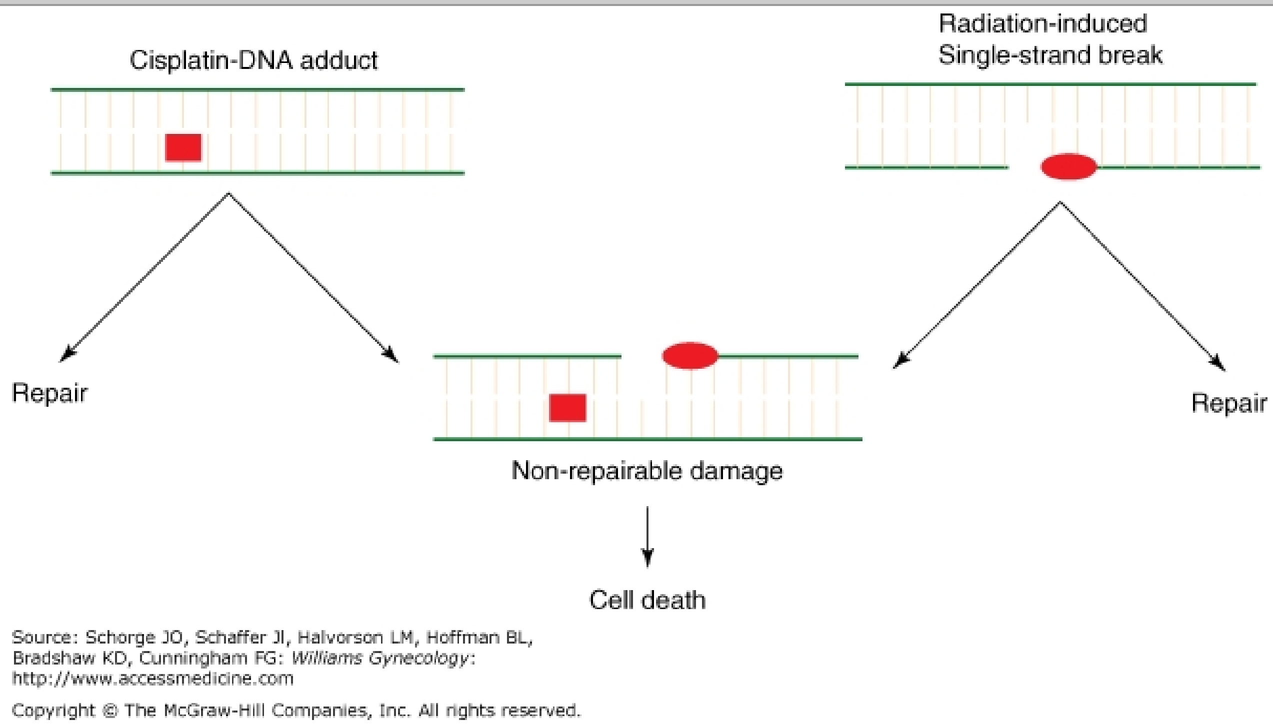
Combination of Ionizing Radiation and Chemotherapy

Ionizing radiation as a single modality rarely controls locally advanced gynecologic cancers. Various factors such as tumor hypoxia, high probability of distant metastasis, and inability of pelvic tissues to tolerate high IR doses are purported causes. For many decades, IR has been combined with chemotherapy or surgery to increase local disease control and decrease distant metastasis. Ionizing radiation and chemotherapy can be administered in a concurrent or alternating fashion. When adding this modality to IR, however, efforts to maximize tumoricidal effects while minimizing overlapping toxicities should be a priority (Steel, 1979). Platinum compounds are most commonly used with IR in the management of gynecologic cancers.

PLATINUM COMPOUNDS

Both IR and cisplatin have DNA as targets causing SSB, DSB, and base damage. Although most lesions are repaired, if a cisplatin-induced adduct is in close proximity with an IR-induced SSB, the damage is irreparable and leads to cell death (Fig. 28-11) (Amorino, 1999; Begg, 1990). In addition, irradiated cell membranes may be more permeable to carboplatin, allowing an increased cellular uptake of the drug (Yang, 1995).

FIGURE 28-11



Model showing response to DNA damage. A cisplatin DNA adduct or a radiation-induced single-strand break is likely repairable. When both occur in close proximity, however, irreparable damage may lead to cell death. *(From Hennequin, 2002, with permission.)*

NUCLEOSIDE ANALOGS

Agents such as fludarabine and gemcitabine inhibit DNA synthesis and metabolism. Cells at the G_1 /S junction of the cycle are involved in DNA synthesis and therefore are blocked from progressing. The remaining cell population, however, is synchronized at the G_2 /M junction and is sensitive to IR. Gregoire and associates (1994, 1999) found that radiation was most effective when IR was delivered 24 to 72 hours after nucleoside analog administration.

TAXANES

The taxanes such as paclitaxel and docetaxel dysregulate microtubule function and block cells at the G_2 /M junction when cells are most sensitive to IR (Mason, 1999).

Combination of Ionizing Radiation and Surgery

Ionizing radiation can be given before, after, or at the time of surgery. With this combination, surgical resection and its associated morbidity can often be minimized yet still achieve tumor control. For example, the combination of IR and surgery in locally advanced vulvovaginal cancer can allow surgeons to avoid extensive surgery, such as pelvic exenteration (Boronow, 1982). Typically, whenever IR is indicated with surgery, some form of chemotherapy is also added in an adjuvant fashion.

PREOPERATIVE RADIATION THERAPY

Primary cancers tend to locally infiltrate surrounding normal tissues with microscopic extension. For this reason, IR can be delivered prior to surgery to decrease the potential of locoregional and distant tumor dissemination as well as the likelihood of positive surgical margins. To sterilize those areas of subclinical infiltration, doses of 40 to 50 Gy given during 4 to 5 weeks are required. Although preoperative RT is not expected to render the main tumor mass cancer-free at the time of surgery, it is common to find no evidence of cancer in the surgical specimen. In patients who presented with unresectable cancers, preoperative RT can transform them into suitable candidates for a surgical attempt (Montana, 2000).

Despite these advantages, administering preoperative RT may unnecessarily expose patients to IR because the true pathologic tumor staging is unknown. Moreover, if the nodal status is normal at the time of surgery, the clinician is faced with the question of whether there initially were lymph nodes containing tumor that were sterilized by the preoperative regimen. This is important, as patients with initially positive lymph nodes tend to develop distant metastasis and typically would require further treatment. Another problem encountered is the management of those patients with pathologically proven residual cancer within the irradiated areas. The pathologist may not be able to adequately ascertain the viability of those residual cells, especially when surgery is performed soon after IR. Therefore, surgery is usually delayed 4 to 6 weeks after completion of IR. By then, the acute reactions from IR have subsided, and pathologic interpretation of the resected specimen is easier.

POSTOPERATIVE RADIATION THERAPY

Often following surgery, a high probability for local recurrence may be predicted by factors such as positive margins, lymph node metastases, lymphovascular invasion, and high-grade cancer. In these cases, postoperative RT may be advantageous and is ideally delivered 3 to 6 weeks following surgery to allow initial wound healing (Sedis, 1999). Because the pathologic stage is known, management can be individualized and unnecessary RT avoided (Rushdan, 2004). The RT fields should encompass the operative bed due to the possibility of tumor contamination at the time of surgery.

INTRAOPERATIVE RADIATION THERAPY

Infrequently, IR can be delivered during surgery by either interstitial brachytherapy or by an electron beam produced by a dedicated linear accelerator installed in the operating room. This technique is indicated in selected patients with recurrent gynecologic cancers. A single dose of 10 to 20 Gy is typically delivered to the area at risk for recurrence or suspected of harboring residual cancer (Gemignani, 2001; Yap, 2005).

Normal Tissue Response to Ionizing Radiation

In general, radiation therapy is less well tolerated when: (1) the volume of tissues irradiated is large; (2) the IR dose is high; (3) the dose per fraction is large; and (4) the patient's age is advanced. Furthermore, a number of other factors can exacerbate the radiation damage to normal tissues. These include previous surgery, concurrent chemotherapy, infection, diabetes mellitus, hypertension, and inflammatory conditions, for example Crohn disease and regional enteritis.

When tissues with a rapid proliferation rate such as epithelium of the small intestine or oral cavity are irradiated, the onset of acute clinical signs and symptoms develop within a few days to weeks. This contrasts with tissues such as muscular, renal, and neural tissues, which have low proliferation rates and may not display signs of radiation damage for months to years after treatment. The concept of tolerance doses for normal tissues was developed as a guide to avoid serious complications in clinical radiation oncology practice.

EPITHELIUM AND PARENCHYMA

Atrophy is the most consistent sequela of radiation therapy and affects all lining epitheliaâ€”including skin and the epithelia of the gastrointestinal, respiratory, and genitourinary tracts and the endocrine glands. Additionally, necrosis and ulceration may develop. The capillary is the most sensitive vessel to IR damage, and ischemia results from damage to the endothelium, rupture of capillary walls, loss of capillary segments, and reduction of microvascular networks. Moreover, in large arteries, atheroma-like calcifications develop (Friedlander, 2003; Zidar, 1997). Histologic changes of the epithelium may also develop, and atypical and dysplastic transformations are the most frequent.

In addition to epithelial changes, fibrosis within the submucosa and deep soft tissues frequently follows IR. This clinically leads to tissue contracture and stenosis (Fajardo, 2005).

SKIN

Four general types of skin reactions may follow radiation therapy. In order of severity, they include erythema, dry desquamation, moist desquamation, and skin necrosis. For many women during a 6- to 7-week IR course, these reactions are common, with the exception of necrosis. Within 1 week following IR, the skin first develops mild erythema. By the third week, redness becomes more pronounced and dry desquamation begins. After 5 to 6 weeks, moist desquamation ensues with epidermal sloughing, followed by

serum and blood oozing through the denuded skin. This reaction is most pronounced in concealed areas of the body, such as the inguinal, axillary, and inframammary regions.

Preventively, throughout and after an IR course, the skin should be kept clean and aerated. For dry desquamative findings, ointments (Aquaphor, Beiersdorf, Hamburg, Germany) or aloe veraâ€"containing creams promote dermal hydration with an emollient effect. In the moist desquamation phase, hydrogen peroxide and water can be used for wound cleaning. Additional skin treatment may include moisturizers (Biafine, Johnson and Johnson, New Brunswick, NJ), whirlpool sessions, sitz baths, and silver sulfadiazineâ€"containing, nonadhering dressings (Vigilon, Bard Medical, Covington, GA) for weeping areas. Importantly, individuals should avoid applying heat pads, soaps, or alcohol-based lotions to irradiated skin.

Regeneration of the epithelium starts soon after IR treatment and is usually complete in 4 to 6 weeks. Months after IR, areas of skin hyper- and hypopigmentation can be seen. The skin remains atrophied, thin, and dry.

VAGINA

Radiation therapy directed to the pelvis commonly leads to acute vaginal mucositis. Although mucosal ulceration is rare, discharge is present in most cases. For these women, a dilute hydrogen peroxide and water solution may provide symptomatic relief. In contrast to acute changes, delayed reactions to IR may include vaginal shortening, atrophic vaginitis, and formation of synechiae or telangiectasia. Preventively, these complications may be avoided if women are instructed regarding the use of dilators or if vaginal intercourse is resumed following treatment. Lastly, rectovaginal or vesicovaginal fistulas can develop after IR, especially in advanced-stage cancers (see Chap. 26, Other Causes).

For those women who remain sexually active following radiation therapy, water-based lubricants (Astroglide, Biofilm, Vista, CA and K-Y Jelly (Johnson and Johnson, New Brunswick, NJ) may be of benefit during intercourse. Unlike lubricants, which have no sustained effects, vaginal moisturizers form a lubricated coating on the vaginal epithelium and retain moisture for 48 to 72 hours. For this reason, vaginal moisturizers (Replens, Lil' Drug Store Products, Cedar Rapids, IA and K-Y Silk-E, Johnson and Johnson, New Brunswick, NJ) can be used regularly at other times to maintain lubricated vaginal tissues. Alternatively, topical estrogen cream may be used to improve atrophic symptoms (see Table 22-7).

Although these products may improve the vaginal changes following radiation treatment, persistent adverse vaginal changes and sexual dysfunction during the 2 years after IR have been documented in a longitudinal study of 118 women who completed radiation therapy for cervical cancer. However, 63 percent of those who engaged in sexual activities before IR therapy continued to do so following treatment, although with less frequency (Jensen, 2003).

OVARY AND PREGNANCY OUTCOMES

The effects of IR on ovarian function depend on the IR dose and patient age. For example, a dose of 4 Gy may cause sterility in 30 percent of young women, but in 100 percent of those older than 40 years. In addition, fractionated IR seems to be more damaging to the ovaries. Ash and colleagues (1980) noted that after 10 Gy given in 1 fraction, 27 percent of women recovered ovarian function compared with only 10 percent of those receiving 12 Gy in 6 days. In patients with gynecologic cancers who receive pelvic IR, symptoms of ovarian failure mirror those of natural menopause and treatment of symptoms is similar (see Chap. 22, Symptoms of Menopause).

To minimize radiation exposure to the ovaries of premenopausal women, these organs may be surgically repositioned, termed *transposition,* out of the radiation field. Despite this maneuver, several investigators have reported high rates of ovarian failure when the ovarian dose was more than 3 to 5 Gy. In addition, a birth incidence of only 19 percent was reported among the patients who could conceive (Chambers, 1991; Haie-Meder, 1993). Among female childhood-cancer survivors who received abdominal irradiation, higher spontaneous abortion rates and lower first-born birth weights were observed compared with cancer survivors who were not irradiated (Hawkins, 1989).

BLADDER

Most patients receiving IR to the pelvis note some symptoms of acute cystitis within 2 to 3 weeks of beginning treatment. Although urinary frequency, spasm, and pain develop commonly, hematuria is rare. Typically, flavoxate hydrochloride (Urispas), oxybutynin (Ditropan), phenazopyridine hydrochloride (Pyridium, Warner Chilcott, Rockaway, NJ) or fluids ad lib promptly relieves symptoms.

Antibiotics may be used when indicated.

Major chronic complications following radiation therapy are infrequent and include bladder contracture and hematuria. For severe hematuria, bladder saline irrigation, transurethral cystoscopic fulguration, and temporary urinary diversion are proven techniques. Hyperbaric oxygen therapy has also been described.

SMALL BOWEL

The small bowel is particularly vulnerable to IR acute early damage. For example, after a single dose of 5 to 10 Gy, the crypt cells are destroyed. The villi become denuded and an ensuing acute malabsorption syndrome causing nausea, diarrhea, vomiting, and crampy pain follows. Antinausea and antidiarrhea medications may be added to general instructions of adequate fluid intake and a low-lactose, low-fat, and low-fiber diet (see Tables 39-13 and 25-5). Additionally, bowel antispasmodics with sedatives (Donnatal, PBM Pharmaceuticals, Gordonsville, VA) are particularly helpful.

Patients should be warned about the late, chronic nature of radiation-induced enteritis. With this, intermittent diarrhea, crampy abdominal pain, nausea and vomiting, which in combination may mimic a low-grade bowel obstruction, are frequent. Those patients with co-morbidities, such as obesity, small vessel diseases resulting from diabetes or hypertension, previous abdominal surgeries, and inflammatory conditions of the pelvis or bowel, are at increased risk.

Preventively, several types of devices have been surgically inserted to displace the small bowel from the pelvis. These have included saline-filled tissue expanders, omental slings, and absorbable mesh (Hoffman, 1998; Martin, 2005; Soper, 1988). Furthermore, defining the areas at risk with surgical clips and careful radiation therapy planning, including the use of IMRT may minimize bowel toxicity (Portelance, 2001). More recent advances include the intravenous use of radiation protectors such as amifostine (Athanassiou, 2003). Amifostine is thought to attenuate radiation cell injury through its ability to reduce levels of radiation-induced free radicals.

RECTOSIGMOID

Commonly, within a few weeks after IR initiation, patients may develop diarrhea, tenesmus, and mucoid discharge, which can be bloody. In these cases, antidiarrheal medications, a low-residue diet, steroid retention enema, and hydration are the mainstays of management. Alternatively, rectal bleeding may be seen months to years after IR treatment. Hemorrhage may at times be severe and require blood transfusion. Moreover, invasive procedures may be needed to control bleeding neovasculature. Steps may include topical application of 4-percent formalin, cryotherapy, and vessel coagulation with laser (Kantsevoy, 2003; Konishi, 2005; Smith, 2001; Ventrucci, 2001). During the evaluation of late-onset rectal bleeding, barium enema is often indicated. The study usually reveals narrowing of the rectosigmoid lumen and wall thickening. In case of severe obstruction, resection of the involved colonic segment is necessary. In addition, rectovaginal fistulas may result from RT (see Chap. 25, Rectovaginal Fistula). Small fistulas may heal over many months following a diverting colostomy.

KIDNEY

Manifestations of acute radiation nephropathy typically appear 6 to 12 months after IR exposure. The patients develop hypertension, edema, anemia, microscopic hematuria, proteinuria, and decreased creatinine clearance (Luxton, 1964). Although deteriorating renal function is occasionally reversible, it usually worsens and leads to chronic nephropathy. Patients receiving concurrent chemotherapy and IR require special consideration, because of the nephrotoxicity associated with many chemotherapy agents (see Chap. 27).

Radiation-Induced Carcinogenesis

Development of a secondary, radiation-induced cancer depends on the age at exposure, dose of IR, and susceptibility of specific tissue types to radiation-induced carcinogenesis (Table 28-4). The accepted criteria for the diagnosis of IR-induced cancer require that the cancer be located within the previously irradiated regions and that its pathology differs from that of the original malignancy. Additionally, there should be a latent period of at least a few years.

Table 28-4 Susceptibility of Selected Tissues to Radiation-Induced Cancer	
Susceptibility	**Tissues**
High	Bone marrow, female breast, thyroid
Moderate	Bladder, colon, stomach, liver, ovary
Low	Bone, connective tissue, muscle, cervix, uterus, rectum

Adapted from Mettler, 1995, with permission.

In general, those receiving higher IR doses and those exposed at an earlier age have increased risks for second malignancies. Secondary tumor development latency also varies depending on the type of second malignancy. For example, the latent period before IR exposure and the clinical appearance of leukemia is less than 10 years, whereas solid tumors may not develop for decades. Of note, for most radiation-induced malignancies, the clinical appearance of these cancers does not appear until the age when non-irradiated patients would spontaneously develop that particular cancer type. Moreover, radiation-induced and spontaneously developing cancer cells have identical pathologic characteristics. The most common example is development of uterine sarcoma years after pelvic radiation for treatment of cervical cancer (Mark, 1996).

PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT: INTRODUCTION

Since the introduction of the Papanicolaou (Pap) test in the 1950s, cervical cytology screening has been associated with a significant reduction in the incidence of and mortality from invasive squamous cervical cancer (Saslow, 2002). Annually, approximately 7 percent of U.S. women who undergo this screening will have abnormal cytologic results requiring a clinical response (Jones, 2000). Accordingly, office gynecology frequently involves the diagnosis and management of lower genital tract (LGT) preinvasive disease.

DISEASE SPECTRUM OF LOWER GENITAL TRACT NEOPLASIA

The term *intraepithelial neoplasia* refers to squamous epithelial lesions of the lower genital tract, which are considered to be cancer precursors, but lack features of invasive cancer. Lesions are diagnosed by biopsy and subsequent histologic evaluation. Cervical, vaginal, vulvar, and perianal intraepithelial neoplasia (CIN, VaIN, VIN, and AIN) demonstrate a disease spectrum ranging from mildly dysplastic cytoplasmic and nuclear changes to those of severe dysplasia. With these changes, there is no invasion through the basement membrane, which defines invasive cancer.

The severity of a lesion is graded according to the proportion of epithelium affected from the basement membrane upwards. In the case of CIN, abnormal cells confined to the lower third of the squamous epithelium are referred to as *mild dysplasia* or *CIN 1;* extending into the middle third as *moderate dysplasia* or *CIN 2;* and into the upper third as *severe dysplasia* or *CIN 3,* with full-thickness involvement called *carcinoma in situ* (CIS). Even though lesions of the vulva and vagina are graded in like fashion, there are recent important changes in terminology regarding the description of vulvar squamous lesions with premalignant potential (New Modified Terminology).

In contrast, being only one cell layer thick, the cervical columnar epithelium does not demonstrate an analogous neoplastic disease spectrum. Histologic abnormalities are therefore limited to *adenocarcinoma in situ* (AIS) or *adenocarcinoma.*

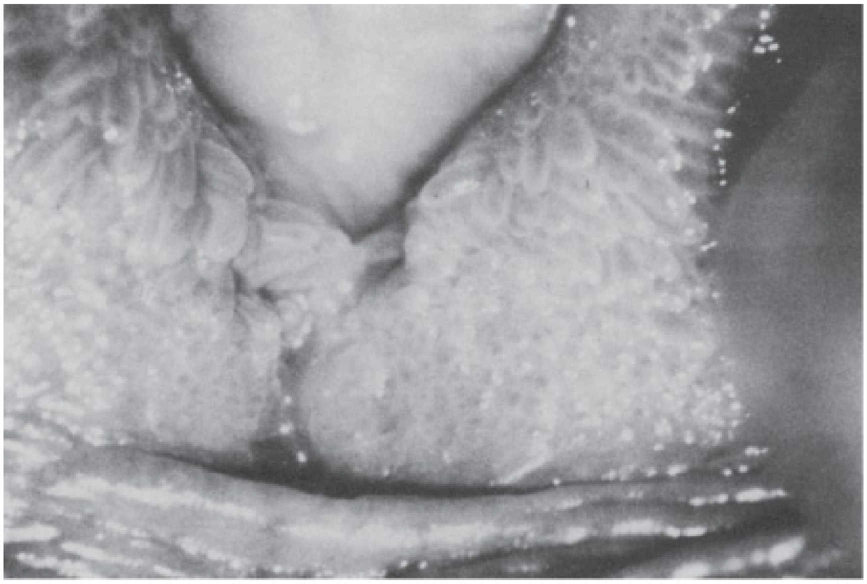
Since the introduction of new cervical cytology terminology in 1988, the term *squamous intraepithelial lesion* (SIL) has become synonymous with intraepithelial neoplasia. Because histologic changes of human papillomavirus (HPV) infection and CIN 1 are similar and cannot be distinguished reliably, they are termed *low-grade squamous intraepithelial lesions* (LSILs), whereas CIN 2 and 3 may be designated as *high-grade SIL* (HSIL) (Saslow, 2002).

ANATOMIC CONSIDERATIONS

External Genitalia

Precancerous lesions of the female LGT are often multifocal, can involve any of its structures, and may appear similar to benign processes. For example, minute epithelial projections, termed *micropapillomatosis labialis,* may be present on the inner labia minora's epithelial surface (Fig. 29-1). Each papillary projection arises from its own individual base. These can be mistaken for HPV-related lesions, which in contrast, tend to be multifocal, asymmetric, and have multiple papillations arising from a single base (Dexeus, 2002; Ferris, 2004). Micropapillomatosis often shows spontaneous regression and treatment is unnecessary (Bergeron, 1990).

FIGURE 29-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Micropapillomatosis labialis is a normal variant of vulvar anatomy encountered along the posterior, inner aspects of the labia minora and lower vagina. In contrast to condylomatous change, projections are uniform in size and shape and arise singly from their base attachments. *(From Bergeron, 1990, with permission.)*

Vagina

The vagina is lined by nonkeratinized squamous epithelium and glands are absent. However, areas of columnar epithelium can occasionally be found within the vaginal squamous mucosa, a condition termed *adenosis.* It is most commonly attributable to in utero exposure to exogenous estrogen during fetal development, particularly diethylstilbestrol (DES) (see Chap. 18, Acquired Uterine Defects) (Trimble, 2001). Careful palpation of the vagina is warranted, as clear cell adenocarcinoma, also associated with DES, may be palpable before it is visible.

Cervix

SQUAMOUS AND COLUMNAR EPITHELIA

Colposcopically, the squamous epithelium of the cervix appears as a featureless, smooth, pale pink surface. Blood vessels lie below this layer and therefore are not visible or are seen only as a fine capillary network. The mucin-secreting columnar epithelium of the endocervix appears red and velvety due to the proximity of blood vessels beneath the one-cell-layer-thick epithelium. The columnar epithelium is characterized by infoldings or clefts and is commonly referred to as "glandular". This is technically incorrect, as true glands, consisting of acini and ducts, are not present (Ulfelder, 1976). Nonetheless, "glandular" abnormalities are reported in the Bethesda nomenclature for cervical cytology (Kurman, 1994).

SQUAMOCOLUMNAR JUNCTION

During embryogenesis, upward migration of stratified squamous epithelium from the urogenital sinus and vaginal plate is thought to replace mÃ¼llerian epithelium (see Chap. 18, Ductal System Development) (Ulfelder, 1976). This process usually ends at the external cervical os, forming the original squamocolumnar junction (SCJ). In a minority, such as those with in utero DES exposure, this migration is incomplete, leading to location of the SCJ in the upper vagina (Kaufman, 2005).

The location of the SCJ varies with age and hormonal status (Fig. 29-2). It everts outward onto the ectocervix during adolescence, pregnancy, and with use of combination hormonal contraceptives. It regresses into the endocervical canal with menopause and

other low-estrogen states such as prolonged lactation and use of progestin-only contraceptives (Anderson, 1991).

FIGURE 29-2

B

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

The location of the squamocolumnar junction (SCJ) is variable. **A.** The SCJ is located on the ectocervix and is fully visualized. **B.** The SCJ is located near the external os and is not entirely visible.

The rise in estrogen at puberty leads to glycogenation of the nonkeratinized squamous epithelium of the LGT. Glycogen provides a carbohydrate source for lactobacilli, which dominate the normal vaginal flora in reproductive-aged women (see Chap. 3). The lactobacilli produce lactic acid, lowering the vaginal pH to less than 4.5. The exposure of the columnar epithelium to this low pH stimulates squamous metaplasia, the conversion of one type of normal epithelium (columnar) into another (squamous).

Squamous metaplasia is a normal process and occurs most actively immediately adjacent to the original SCJ, creating a zone of metaplastic epithelium termed the *transformation zone* (TZ), between the original SCJ and the columnar epithelium.

TRANSFORMATION ZONE AND CERVICAL NEOPLASIA

Nearly all cervical neoplasia, both squamous and columnar, develops within the transformation zone, usually adjacent to the new SCJ (Anderson, 1991). Theoretically, cervical cells undergoing metaplasia are particularly vulnerable to the oncogenic effects of HPV and co-carcinogens. Metaplasia is most active during adolescence and pregnancy. This may explain why early age of sexual activity and first pregnancy are known risk factors for cervical cancer.

HUMAN PAPILLOMAVIRUS

The role of this virus in the genesis of essentially all cervical neoplasia and a significant portion of vulvar, vaginal, and anal neoplasia is firmly established.

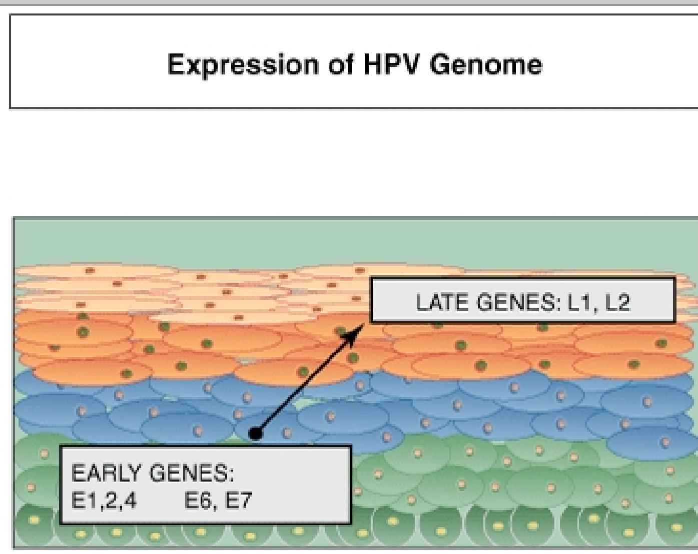
Basic Virology

Human papillomavirus is a nonenveloped DNA virus with a protein capsid. It infects epithelial cells exclusively and approximately 30 to 40 HPV types have an affinity for infecting the lower anogenital tract.

VIRAL LIFE CYCLE

The circular, double-stranded HPV genome consists of only nine identified open reading frames (ORF) (Southern, 1998). The "early" (E) genes govern functions early in the viral life cycle such as DNA maintenance, replication, and transcription. The "late" (L) genes encode capsid proteins needed late in the viral life cycle to complete assembly into new, infectious viral particles (Beutner, 1997; de Villiers, 2004). Completion of the viral life cycle takes place only within an intact squamous epithelium. Early genes are expressed in the lower layers and late genes are expressed in the more superficial layers, in synchrony with epithelial differentiation. Viral replication is completed within the most superficial epithelial layers. HPV is a nonlytic virus, and therefore infectiousness depends upon desquamation of infected cells (Fig. 29-3) (Doorbar, 2005).

FIGURE 29-3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

The human papillomavirus life cycle is completed in synchrony with squamous epithelium differentiation. Early genes, including the *E6* and *E7* oncogenes, are expressed most strongly within the basal and parabasal layers. The late genes encoding capsid proteins are expressed later in the superficial layers. Intact virus is shed within superficial squama. Late genes are not strongly expressed in high-grade neoplastic lesions.

VIRAL TYPES

More than 100 HPV types have now been identified. Clinically, HPV types are classified as high-risk (HR) or low-risk (LR) based upon their cervical cancer oncogenicity. Low-risk HPV types 6 and 11 cause nearly all genital warts and a minority of subclinical HPV infections. Low-risk HPV infections are rarely, if ever, oncogenic.

In contrast, the HR HPV types include 16, 18, 31, 33, 35, 45, and 58 and account for approximately 95 percent of cervical cancer cases worldwide. Other HR HPV types less often associated with neoplasia include 39, 51, 52, 56, 59, 68, 73, and 82 (Bosch, 2002; Lorincz, 1992; Munoz, 2003).

The most common HR HPV types (16, 18, 45, and 31) found in cervical cancer are also the most prevalent in the general population. Specifically, HPV 16 is the dominant cancer-related HPV, accounting for 40 to 70 percent of invasive squamous cell cervical cancers worldwide (Bosch, 2002; Munoz, 2003). This serotype is also the most common HPV found among low-grade lesions and in women without neoplasia (Herrero, 2000).

Like HPV 16, viral types 18, 45, and 56 are also highly oncogenic (Lorincz, 1992). The prevalence of HPV 18 is much lower than that of HPV 16 in the general population, but it is found in up to 25 percent of squamous cell carcinomas, and in an even higher proportion of cervical adenocarcinomas and adenosquamous carcinomas (Ferris, 2004).

Additionally, HPV 18 is thought to play a dominant role in the development of rapid transit cervical cancers, that is, those that appear to develop without the prolonged premalignant phase typical of most cervical cancers. These cancers develop within 1 to 3 years of negative cervical cytology, are more likely to be adeno- or adenosquamous, and develop in younger women (Hildesheim, 1999; Lorincz, 1992; Schwartz, 1996). However, the existence of rapid transit lesions remains controversial, as these may actually reflect late-detected endocervical disease, which is more likely to be missed by cytologic screening (Schwartz, 1996).

Transmission

Transmission of genital HPV usually requires sexual contact with the genital skin, mucous membranes, or body fluids of a partner with either warts or subclinical infection (Abu, 2005; American College of Obstetricians and Gynecologists, 2005b). Exceptions are considered to be extremely rare.

Little is known about the infectivity of subclinical HPV, but it is assumed to be high, especially in the presence of high viral counts. Through microabrasion of the genital epithelium during sexual contact, HPV likely gains access to the basal cell layer. Once infected, the basal cells become a viral reservoir.

Genital HPV infection is multifocal, involving more than one lower reproductive tract site in most cases (Bauer, 1991; Campion, 1991; Spitzer, 1989). Therefore, neoplasia at one genital site increases risk of neoplasia elsewhere within the lower genital tract.

MODES OF TRANSMISSION

High-risk HPV cervical infection is not seen in women who have not experienced penetrative sexual contact, although they may occasionally test positive for non-oncogenic or low-risk types at the vulva or vagina, perhaps due to vaginal tampon use or digital penetration (Andersson-Ellstrom, 1996; Fairley, 1992; Ley, 1991; Rylander, 1994; Winer, 2003).

Oral-genital and hand-genital transmissions are possible, but appear to be far less common than with genital-genital, particularly penile-vaginal penetrative contact (Winer, 2003). Nonsexual transmission of genital HPV types is theoretically possible, but is probably rare in sexually active adults. Fomite transmission, known to occur with nongenital warts, is unproven (Ferenczy, 1989).

Women who have sex with women frequently report past sexual experiences with men. This subgroup of women have rates of HR-HPV positivity, abnormal cervical cytology, and high-grade cervical neoplasia similar to those of heterosexual women, but undergo cervical cancer screening less often (Marrazzo, 2000). Those who have never had sex with men appear to be at similar risk, implying that digital, oral, and object contact place them at risk of HPV infection. Therefore, women who are sexually active should undergo cervical cancer screening according to current recommendations regardless of sexual orientation.

CONGENITAL INFECTION

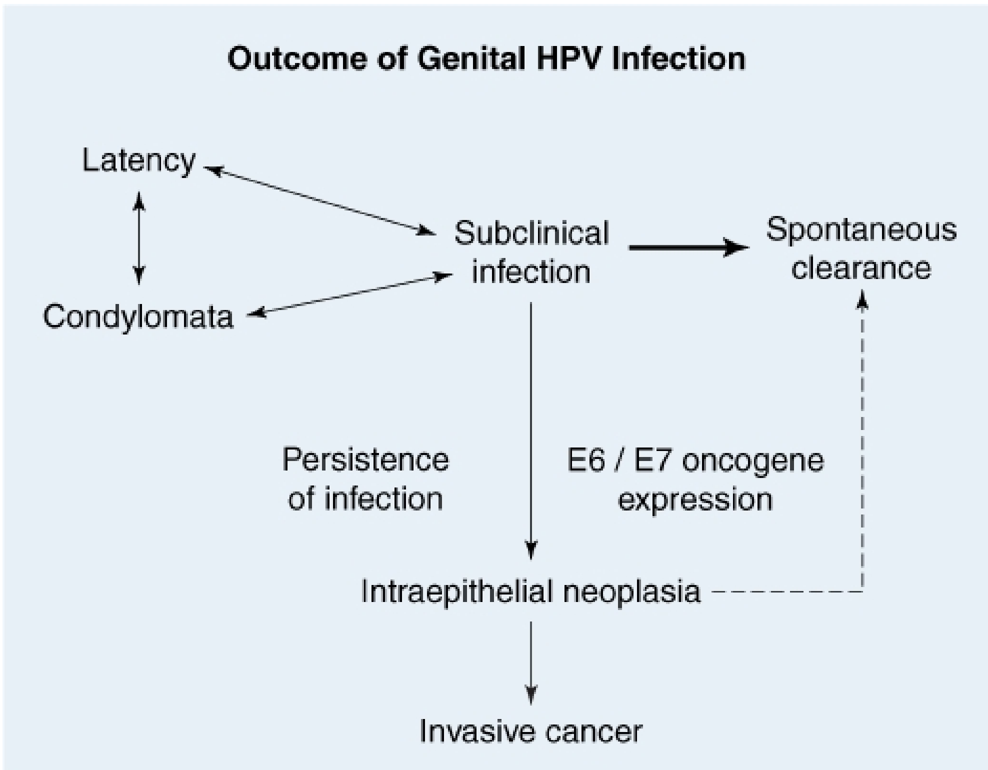
Congenital HPV infection by vertical infection from mother to infant develops rarely. Conjunctival, laryngeal, vulvar, or perianal warts present at birth or that develop within 1 to 3 years of birth are most likely due to perinatal exposure to maternal HPV in the absence of sexual abuse (Cohen, 1990). Infection is not related to the presence of maternal genital warts or route of delivery (Silverberg, 2003; Syrjanen, 2005). Accordingly, cesarean delivery is recommended for HPV-related infection only in cases of large genital warts that would likely obstruct delivery or avulse with cervical dilation.

Genital warts that develop in children after infancy are always cause to seriously consider sexual abuse. However, infection by nonsexual contact, autoinoculation, or fomite transfer is also possible, as evidenced by the finding of nongenital HPV types in a significant minority of cases (Cohen, 1990; Obalek, 1990; Siegfried, 1997).

Outcome of HPV Infection

Genital HPV infection results in a variety of outcomes (Fig. 29-4). Infection may be *latent* or *expressed.* Expression is either *productive,* with formation of new virus, or *neoplastic,* causing preinvasive disease or malignancy. Most productive and neoplastic infections are subclinical, rather than clinically apparent, as with genital warts or obvious malignancy. Finally, HPV infection can be *transient* or *persistent.* Neoplasia is the least common outcome of genital HPV infection.

FIGURE 29-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

The natural history of genital HPV infection is variable between individuals and over time. Subclinical infection and spontaneous resolution of apparent infection are the most common outcomes. Neoplasia is the least common manifestation, usually developing over years as the result of persistent infection.

LATENT INFECTION

Latent infection refers to that in which cells are infected, but HPV remains quiescent. There are no tissue effects, as the virus is not reproducing. Little is known about the incidence, natural history, or significance of latent HPV infection, as the virus is present below detectable levels.

EXPRESSED PRODUCTIVE INFECTION

Productive infections have little or no malignant potential because eventual host cell death is required to complete the viral life cycle. The intact, circular HPV genome remains unintegrated into the infected cell's chromosomes and its oncogenes are expressed at only very low levels (Durst, 1985; Stoler, 1996).

In both the female and male genital tracts, productive HPV infections produce either visible genital warts, called *condylomata acuminata,* (see Chap. 3, External Genital Warts) or much more commonly, subclinical infections known as low-grade squamous intraepithelial lesions (LSILs).

EXPRESSED NEOPLASTIC INFECTION

In cancerous lesions, the circular HPV genome integrates linearly at random locations into a host chromosome and unrestrained transcription of the E6 and E7 oncogenes follows (Durst, 1985; Stoler, 1996). Their products, the E6 and E7 oncoproteins, interfere with the function and accelerate degradation of p53 and pRB, key host tumor suppressor proteins. This leaves the infected cell vulnerable to malignant transformation by loss of cell cycle control, cellular proliferation, and accumulation of DNA mutations (Doorbar, 2005).

In preinvasive lesions, normal epithelial differentiation is modified. The degree of abnormal epithelial maturation that results is used to grade lesion histology as mild, moderate, or severe cervical intraepithelial neoplasia. The average age at diagnosis of low-grade cervical disease is younger than that of high-grade lesions and invasive cancers, and it has long been assumed that a disease continuum exists. An alternative theory proposes that low-grade lesions are generally transient and non-oncogenic, whereas high-grade lesions and cancers are monoclonal, arising de novo without prerequisite low-grade disease (Baseman, 2005; Kiviat, 1996). This may explain why some cancers are diagnosed soon after negative cytologic screening.

Natural History of Human Papillomavirus Infection

Infection with HPV, predominantly HR types, is common very soon after initiation of sexual activity (Brown, 2005; Winer, 2003). However, this phenomenon is by no means confined to sexually promiscuous adolescent populations. Collins and colleagues (2002) conducted a longitudinal study of 242 women recruited within 6 months of beginning their first sexual relationship and who remained monogamous to their one sexual partner. During 3 years of surveillance, 46 percent acquired cervical HPV infection. Median time to infection was less than 3 months.

Especially in adolescents and young women, most HPV lesions, whether clinical or subclinical, spontaneously regress, (American College of Obstetricians and Gynecologists, 2005a; Fine, 1998; Ho, 1998). Several studies show that LR HPV infections resolve faster than those involving HR HPV (Moscicki, 2004; Schlecht, 2003; Woodman, 2001). Younger women frequently change HPV types, reflecting transience of infection and sequential re-infection by new partners rather than persistence (Ho, 1998; Rosenfeld, 1992).

Estimates of short-term risk of progression from incident HPV infection to high-grade neoplasia in young women range from 3 to 31 percent (Moscicki, 2004; Wright, 2005). The risk of progression to high-grade neoplasia increases with age, as HPV infection in older women is more likely to be persistent (Hildesheim, 1994).

INCIDENCE

Genital HPV is the most common sexually transmitted infection. Worldwide, populations vary in point prevalence from 2 to 44 percent. The Centers for Disease Control and Prevention (2002) estimates that the risk of a woman acquiring genital HPV by age 50 is greater than 80 percent. The prevalence of genital warts is approximately 1 percent and cytologic abnormalities 4 to 5 percent, with both more common in high-risk groups. Thus, inapparent, that is, subclinical, infection is far more common than genital warts (Koutsky, 1997). Most incident HPV infections occur in young women and adolescents under age 25.

RISK OF INFECTION

The strongest risk factors for the acquisition of genital HPV infection are the number of lifetime and recent sexual partners and early coitarche, that is, age of first sexual intercourse (Burk, 1996; Fairley, 1994; Franco, 1995; Ley, 1991; Melkert, 1993; Schiffman, 1994).

Diagnosis of Infection

Infection with HPV is suspected by the appearance of clinical lesions and through the results of cytology, histology, and colposcopy, all of which are subjective and often inaccurate. In addition, serology is unreliable and unable to distinguish past from current infection (Carter, 2000; Dillner, 1999). Therefore, a definitive diagnosis can be made only by the direct detection of HPV DNA. This

can be done histologically by in situ hybridization, by nucleic acid amplification via polymerase chain reaction (PCR), or by hybrid capture (HC) techniques (Molijn, 2005). Currently, Hybrid Capture 2 (Digene Corporation, Gaithersburg, MD) is the most common technique in clinical use. It is a chemiluminescent test that uses a mixture of RNA probes for the detection of 13 oncogenic HPV types.

Clinical HPV testing by HC 2 can be carried out by collection of cervical cells using a small brush device or in conjunction with liquid-based cytology. If a typical wart in a young woman is found or if high-grade cervical neoplasia or invasive cancer is identified by cytology or histology, then HPV infection is assumed and confirmation by HPV testing is not necessary. Routine testing for HPV is not currently indicated outside of cervical cancer screening and triage or surveillance of abnormal cytologies.

Treatment

The only indications to treat HPV-related lower genital tract disease are the presence of neoplasia or symptomatic warts that cause physical discomfort or psychological distress. Again, most HPV infection is transient, and warts have a spontaneous regression rate of 60 to 70 percent.

A variety of treatment modalities are available and are chosen according to size, location, and number of warts. Mechanical removal or destruction, topical immunomodulators, and chemical or thermal coagulation can be used (see Chap. 3, Treatment). There is no effective treatment for subclinical HPV infection. Physical damage can be done to the LGT in attempting to eradicate HPV infections, which are usually self-limited.

Examination of a male partner does not benefit a female partner either by influencing re-infection or by altering the clinical course or treatment outcome for genital warts or LGT neoplasia (Centers for Disease Control and Prevention, 2002; Howe, 2001).

Prevention

BEHAVIORAL INTERVENTIONS

Sexual abstinence, delaying coitarche, and limiting the number of sexual partners are the most logical strategies to avoid or limit genital HPV infection and its effects. However, evidence from trials of counseling and sexual practice modification is lacking.

CONDOMS

Use of condoms is recommended for prevention of sexually transmitted infections (STIs) in general, but their efficacy specifically in preventing HPV transmission is less certain. Male condoms are more effective at preventing STIs transmitted through body fluids and across mucosal surfaces, and less so for STIs spread skin-to-skin, as is the case with HPV (Centers for Disease Control and Prevention, 2002). However, Winer and associates (2003) conducted the first prospective study of male condom use and HPV risk in young women and showed reductions in HPV infection even if condoms were not consistently used.

VACCINES

Development of vaccines offers the greatest promise for prevention of HPV infection and perhaps limiting or reversing its sequelae in those already infected.

Immunology of Human Papillomavirus Infection

Immune response appears to be a key determinant of HPV epidemiology and oncogenicity. At present, the immunology of HPV is only partially characterized, but it appears that local and humoral immunity protect against initial infection. Cell-mediated immunity likely plays the larger role in HPV infection persistence, as well as progression or regression of benign and neoplastic lesions.

Prophylactic Vaccines

Prophylactic vaccines elicit humoral antibodies that neutralize HPV before it can infect host cells (Christensen, 2001). Although they do not prevent transient HPV positivity, they do prevent establishment of persistent infection and therefore, the development of cervical neoplasia.

In four randomized, masked, placebo-controlled studies totaling over 20,000 subjects, a recombinant quadrivalent vaccine against

types 6, 11, 16, and 18 (Gardasil, Merck & Co., Inc., Whitehouse Station, NJ) has shown 90- to 100-percent protection against genital warts plus vulvar, vaginal, and cervical neoplasia in women who are serology and genital tract PCR negative for the HPV types covered (U.S. Food and Drug Administration, 2006). In 2006, Gardasil received Food and Drug Administration (FDA) approval for vaccination of girls and women aged 9 to 26 years. A bivalent HPV 16/18 vaccine (Cervarix, GlaxoSmithKline, Brentford, UK) has shown similar efficacy and is anticipated to receive similar approval upon completion of its phase III trial (Harper, 2006).

Administered in three intramuscular doses during a 6-month period, both vaccines are extremely safe and well tolerated (Harper, 2006; Mao, 2006). Vaccination strategies should emphasize administration prior to coitarche when protection provided is nearly 100 percent. However, a history of previous sexual intercourse or HPV-related disease is not a contraindication to vaccine administration because exposure to the HPV types targeted by the vaccines is not certain. Testing for HPV is not recommended prior to vaccination. The Advisory Committee on Immunization Practices recommends that HPV vaccination be administered routinely to girls aged 11 to 12 years and is allowed for 9- to 26-year-old individuals whether or not they have been sexually active (American College of Obstetricians and Gynecologists, 2006b; Centers for Disease Control and Prevention, 2002).

Therapeutic Vaccines

The development of effective therapeutic vaccines for the mitigation or eradication of established HPV-related disease, including genital warts, preinvasive lesions, and invasive cancer, presents far greater challenges. The cell-mediated immunology of HPV is more complex and less understood than humoral immunity. Persistent HPV infection in any form is indication that the host-HPV interaction has evaded immune responsiveness. Current research and clinical trials are reviewed by Padilla-Paz (2005).

CERVICAL INTRAEPITHELIAL NEOPLASIA

Incidence

Of the 4 to 5 percent of Pap tests with epithelial abnormalities found annually during screening in the U.S., perhaps half represent any degree of histologic cervical intraepithelial neoplasia (CIN). The incidence of CIN will vary by population studied, as it is strongly related to younger age, socioeconomic factors, and risk-related behaviors. Moreover, its true incidence and prevalence can only be estimated, as screening cytology and colposcopy lack complete sensitivity.

Natural History

Few CIN lesions have the potential to progress to frankly invasive cancer. Progressive potential increases with CIN grade. For example, Hall and Walton (1968) observed progression to CIS in 6 percent of histologic "slight" dysplasias, 13 percent of moderate dysplasias, and 29 percent of "marked" dysplasias. Slight dysplasia regressed or disappeared in 62 percent, but did so in only 19 percent of those with marked disease. A review of natural history studies spanning 40 years and combining heterogeneous data provides estimates of CIN progression, persistence, and regression (Table 29-1) (Ostor, 1993).

Table 29-1 Natural History of Cervical Intraepithelial Neoplasia Lesions

	Regression (%)	Persistence (%)	Progression to CIS (%)	Progression to Invasion (%)
CIN 1	57	32	11	1
CIN 2	43	35	22	5
CIN 3	32	<56	â€“	>12

CIN = cervical intraepithelial neoplasia; CIS = carcinoma in situ.

From Ostor, 1993, with permission.

Risk Factors

Identifiable risk factors for cervical intraepithelial neoplasia are similar for invasive lesions and prove useful in the development of cervical cancer screening and prevention programs (Table 29-2). Ultimately, the risk of neoplasia is most strongly related to: (1)

infection with a HR HPV type, (2) older age, and (3) most importantly, persistence of the HR HPV infection (Elfgren, 2005; Ho, 1995; Koutsky, 1992; Kjaer, 2002; Lorincz, 1992; Remmink, 1995; Schiffman, 2005; Wallin, 1999). However, a constellation of other poorly defined demographic, behavioral, and medical risk factors for cervical neoplasia have been identified, varying widely among populations worldwide.

Table 29-2 Risk Factors for Cervical Neoplasia
Demographic risk factors
Ethnicity (Latin American countries, U.S. minorities)
Low socioeconomic status
Age
Behavioral risk factors
Infrequent or absent cancer screening Pap tests
Early coitarche
Multiple sexual partners
Male partner who has had multiple sexual partners
Tobacco smoking
Dietary deficiencies
Medical risk factors
Cervical high-risk human papillomavirus infection
Parity
Immunosuppression

AGE

In the United States, the median age of cervical cancer diagnosis is the middle to late forties, approximately a decade later than CIN. Theoretically, HPV infection in an older woman is more likely to be persistent than transient. Older age also allows accumulation of mutations that can lead to cellular malignant transformation. Additionally, decreased needs for prenatal care and contraception cause older women to access cancer prevention programs less often.

BEHAVIOR

The most consistently recognized behavioral risks for cervical neoplasia are noted in Table 29-2 (Brinton, 1992; Suris, 1999). Such behaviors increase the risk of acquiring oncogenic HPV infection. For many years, epidemiologic evidence has linked sexual behavior such as early coitarche, multiple sexual partners, and male partner promiscuity with cervical neoplasia (Buckley, 1981; de Vet, 1994; Kjaer, 1991).

TOBACCO SMOKING

Tobacco smoking increases the risk of cervical cancer among HPV-positive women (Bosch, 2002; Plummer, 2003). Nicotine and its major metabolite cotinine are found in the cervical mucus of women and in the semen of men who smoke. These chemicals may cause alterations that promote HPV-driven cellular transformation and neoplasia. In a case-controlled study, Becker and colleagues

(1994) implicated current smoking, high-number pack-years of use, and smoking at the time of menarche as etiologic factors associated with neoplasia. Accruing evidence may soon prompt the addition of cervical cancer to the list of tobacco-associated cancers with tobacco smoke proving to be an independent carcinogen.

DIETARY DEFICIENCIES

Although data are inconclusive, dietary deficiencies of certain vitamins such as A, C, E, beta carotene, and folic acid may alter cellular resistance to HPV infection, promoting viral infection persistence and cervical neoplasia (Paavonen, 1990). However, in the U.S., lack of association between dietary deficiencies and cervical disease may reflect the relatively sufficient nutritional status of even lower-income women (Amburgey, 1993).

MEDICAL RISK FACTORS

Combination Oral Contraception (COC) and Parity

Study results linking cervical neoplasia and these risk factors are conflicting. It has been reported that steroid hormones found in COC may affect the HPV genome and increase viral expression of oncoproteins E6 and E7 (de Villiers, 2003). During pregnancy, immunosuppression and hormonal influences on cervical epithelium combined with trauma related to vaginal deliveries have been suggested as etiologic factors associated with the development of cervical neoplasia (Brinton, 1990).

However, analysis of young women enrolled in the Atypical Squamous Cell/Low-grade Squamous Intraepithelial Lesion Triage Study (ALTS) found that noninjectable hormonal contraceptives, pregnancy, and parity had little effect on acquisition of high-risk HPV infection or development of CIN 3 (Castle, 2005). Moreover, epithelial cell cancers are generally not influenced by hormonal factors.

Immunosuppression

Studies consistently suggest that HIV-positive women have much higher rates of CIN compared with HIV-negative women (Ellerbrock, 2000; Wright, 1994). In women infected with HIV, up to 60 percent of Pap smears exhibit cytologic abnormalities and as many as 40 percent have colposcopic evidence of dysplasia. In addition, transplant recipients treated with immunosuppressive medications have a 5- to 6-percent risk of developing a neoplasm after transplantation, and most of these neoplasms are associated with oncogenic DNA viruses.

INADEQUATE SCREENING

Cervical cancer prevention requires cytologic identification and then eradication of cancer precursor or early invasive lesions. A report reviewing the screening histories of 481 women with invasive cervical cancer in Connecticut from 1985 through 1990 found that 52 percent of women had histories of suboptimal screening: 28.5 percent had never been screened, and 23.5 percent of those screened had their last Pap test 5 or more years before their cancer diagnosis (Janerich, 1995).

Differential Diagnosis and Evaluation of Cervical Lesions

In general, preinvasive lesions of the LGT are not visible to unaided inspection. The exception to this is VIN 3, which is often visible or palpable or both. Oddly, only cervical lesions at either end of the neoplastic disease spectrum are visible: condylomata and invasive cancers. Accordingly, all grossly visible cervical lesions, particularly ulcers, erosions, or leukoplakias, are justification for colposcopic examination and biopsy.

Cervical Cytology

Cervical cytologic screening is one of modern medicine's greatest success stories. The Pap test detects most cervical neoplasia during the usually prolonged premalignant or early occult malignant phases when treatment outcome is optimized.

EFFICACY OF CERVICAL CANCER SCREENING

The Pap test has never been evaluated in a randomized, controlled, or masked trial (Koss, 1989). However, countries with organized screening programs have consistently realized a dramatic decline, generally 60 to 70 percent, in both cervical cancer incidence and mortality (Noller, 2005; World Health Organization, 2006). The Pap test's specificity is consistently high, approximating 98 percent. However, estimates of its sensitivity are lower and more variable. A recent meta-analysis found a

sensitivity of 51 percent (95 percent confidence interval; 0.37 to 0.66) for detection of any grade of CIN by a single Pap test, but a higher sensitivity for high-grade lesions (Agency for Health Care Policy and Research, 2006). The Pap test is thought to be less sensitive for the detection of adenocarcinomas than for squamous lesions. Eighty percent of cervical cancers are squamous, whereas 15 percent are adenocarcinomas (Moore, 2006).

Women should be aware of the imperfect sensitivity of the Pap test and the need for periodic screening to compensate. Providers likewise should use the Pap test appropriately as a screening test in asymptomatic women. Physical signs or symptoms suspicious for cervical cancer should be evaluated with diagnostic studies such as colposcopy and biopsy.

Although up to 70 percent of cervical cancer cases in screened populations are associated with either inadequate screening or surveillance of abnormal results, 30 to 40 percent develop in screened women (Carmichael, 1984). False-negative Pap tests may result from sampling error, in which abnormal cells are not present in the Pap test; from screening error, in which the cells are present but missed by the screener; or from interpretation error, in which abnormal cells are misclassified as benign (Wilkinson, 1990). Although quality assurance measures and new computerized screening technologies address the latter two factors, clinicians can favorably impact the sensitivity of the Pap test by obtaining an optimal cytologic specimen.

CERVICAL SCREENING TECHNOLOGIES

Conventional Pap Collection

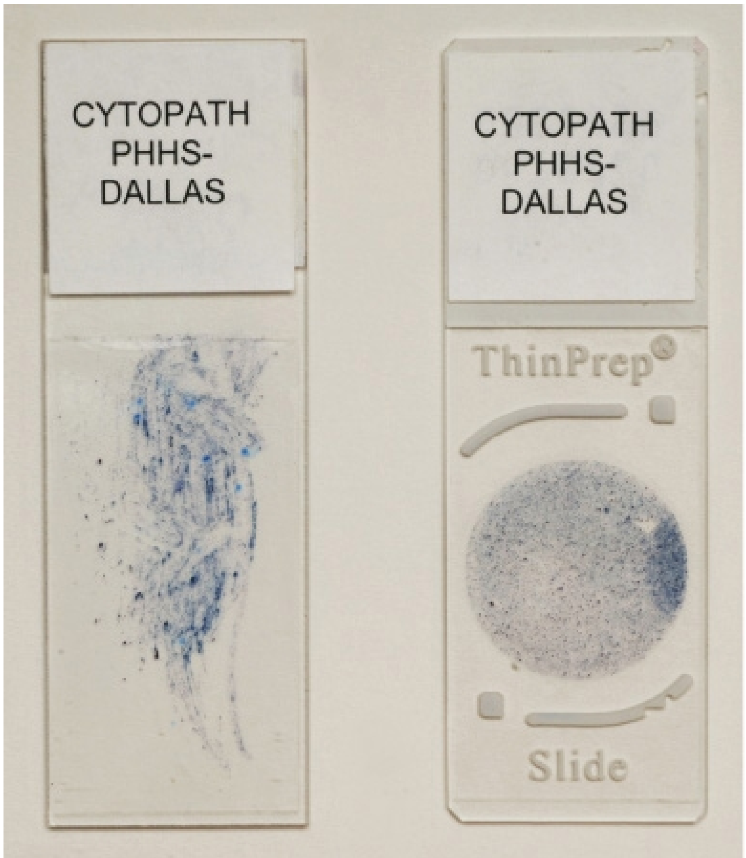
There are presently two cervical cytology techniques in use: conventional and liquid-based. The conventional Pap test is a smear of cells made directly from collection device to glass slide at the time of sampling. Goodman and Hutchinson (1996) demonstrated that most cellular material remains on the collection device and is discarded after a single conventional smear is prepared. Although examination of the excess material ordinarily discarded did not result in additional diagnoses of HSIL or cancer, the discarding of most cervical material sampled has raised concern with this method.

Liquid-Based Pap Collection

The imperfect sensitivity and variable smear quality of conventional Pap collection have driven the development of thin-layer liquid-based cytology (LBC) during the past decade. Liquid-based cytology collects cells in a liquid transport medium that is subsequently processed to produce an even monolayer of cells on a glass slide. There are currently two LBC products marketed in the U.S.: ThinPrep 2000 (Cytyc Corp., Boxborough, MA) and SurePath (TriPath Imaging, Inc., Burlington, NC). Both products are FDA approved as alternatives to the conventional Pap test.

The number of cells, between 50,000 and 75,000, and the area of the slide covered with cells are less than with a conventional smear. However, obscuring blood, mucus, debris, and cellular overlap are largely eliminated. Theoretically, abnormal cells that might be few in number, clustered, and obscured on a conventional smear will be randomly and evenly distributed over the area of the LBC slide and thus be more visible for detection (Fig. 29-5). In addition, most or all of the collected cellular material is available for laboratory processing and is not discarded in the sampling process.

FIGURE 29-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Conventional cervical cytology is prepared by smearing collected cells directly onto a glass slide with the collection device followed by immediate fixation (**left slide**). Thin-layer liquid-based cytology involves transfer of collected cells from collection device into a liquid transport medium with subsequent processing and transfer onto a glass slide. Cells are distributed over a smaller area and debris, mucus, blood, and cell overlap are largely eliminated (**right slide**). *(Courtesy of Dr. Raheela Ashfaq.)*

Residual LBC specimens can undergo testing for HPV, herpes simplex virus, *Neisseria gonorrhoeae,* and *Chlamydia trachomatis.* ThinPrep is FDA approved for reflex HPV testing and it is possible that SurePath will gain similar approval in the future.

PERFORMING A PAP TEST

Preparation

Ideally, Pap tests should be scheduled to avoid menstruation. Patients should abstain from vaginal intercourse, douching, and use of vaginal tampons and medicinal or contraceptive cream preparations for a minimum of 24 to 48 hours before a test. Treatment of cervicitis or vaginitis prior to Pap testing is optimal. However, Pap testing should never be deferred due to unexplained inflammatory conditions or bleeding, as these signs and symptoms may be caused by cervical or other genital tract cancers. Pap screening should be performed on high-risk patients whenever an opportunity arises.

Complete clinical information is essential to accurate interpretation of a Pap test and includes documenting the date of last menstrual period or pregnancy, exogenous hormone use, menopausal status, and past history of abnormal bleeding or abnormal Pap test results, dysplasia, or cancer. Additionally, intrauterine devices (IUDs) can cause reactive cellular changes and their use should be noted. Important risk factors such as immunosuppression, recent immigration from an underdeveloped country, or prior

lack of adequate screening may be helpful.

Adequate visualization of the cervix is essential for detection of gross lesions and identification of the SCJ. Touching the cervix should be avoided prior to performing a Pap, as dysplastic epithelium, particularly high-grade lesions, may be inadvertently removed with minimal trauma. Discharge covering the cervix may be carefully removed with a large swab, preferably without touching the cervix. Vigorous blotting or rubbing may cause scant cellularity or a falsely negative Pap test result. When indicated, additional cervical sampling to detect infection should be performed after Pap testing.

Location

Sampling of the transformation zone is paramount to the sensitivity of the Pap test. Technique should be adapted and sampling devices chosen according to the location of the squamocolumnar junction which varies widely with age, obstetric trauma, and hormonal status (Squamocolumnar Junction). Women known or suspected of in utero DES exposure may also benefit from a separate Pap test of the upper vagina, as these women are at additional risk for vaginal cancers (see Chap. 18, Acquired Uterine Defects) (Kaufman, 2005; Palmer, 2002).

Sampling Tools

Three types of devices are commonly used to sample the cervix: the spatula, the broom, and the endocervical brush (Saslow, 2002; Spitzer, 1998). A spatula predominantly samples the ectocervix. An endocervical brush samples the endocervical canal and is used in combination with a spatula. A broom samples both endo- and ectocervical epithelia simultaneously.

A spatula is oriented to best fit the cervical contour, straddle the squamocolumnar junction, and sample the distal endocervical canal. A clinician firmly scrapes the cervical surface completing at least one full rotation. For spatulas, plastic is preferred to wood because cells are more easily released from a plastic surface.

The endocervical brush, with its conical shape and plastic bristles, has largely replaced the moistened cotton swab to sample the endocervical canal because of its superior ability to collect and release endocervical cells (Koonings, 1992; Martin-Hirsch, 2001; Taylor, 1987). After the spatula sample is obtained, the endocervical brush is inserted into the endocervical canal only until the outermost bristles remain visible. This prevents inadvertent sampling of lower uterine segment cells, which can appear falsely atypical. To avoid excessive bleeding, the brush is rotated only one-quarter to one-half turn. If the cervical canal is wide, as in parous women, the brush is moved to contact all surfaces of the entire endocervical canal.

Broom devices have longer central bristles that are inserted into the endocervical canal. These longer bristles are flanked by shorter bristles that splay out over the ectocervix during multiple clockwise rotations. The recommended number of broom rotations varies by manufacturer. Broom devices are favored for LBC.

Conventional Slide Testing

This cytology method requires special care to avoid air drying of cells, a leading cause of poor slide quality. The spatula sample should be held while the endocervical brush sample is taken. The spatula sample is then quickly spread as evenly as possible over one half to two thirds of a glass slide. The endocervical brush is firmly rolled over the remaining area of the slide, after which fixation is carried out immediately by spray or immersion.

Liquid-Based Testing

Sampling and cell transfer to a liquid medium should be performed according to manufacturer specifications. SurePath allows for the use of all three device types, but with modified device tips that can be broken off and sent to the laboratory in the liquid medium. ThinPrep requires immediate and vigorous agitation of the chosen collection device in the liquid medium, after which the device is discarded.

COMPARISON OF CONVENTIONAL AND LIQUID-BASED CYTOLOGY

Liquid-based cytology now accounts for most of Pap tests performed in the U.S. Both LBC products are FDA-approved to claim a 65-percent increased detection rate of HSIL compared with conventional smears, as well as decreased unsatisfactory sample rates. Furthermore, there is evidence that LBC is more sensitive and accurate for the detection of both squamous lesions and adenocarcinomas of the cervix (Ashfaq, 1999; Chhieng, 2004). Comparison studies show variable results with respect to atypical

squamous cell detection rates.

Although the preponderance of numerous studies show an increase in sensitivity by LBC technology, controversy exists about data significance because of study methodologies (Baker, 2002; Bernstein, 2001; Braly, 2001; Hutchinson, 1999). Ronco and colleagues (2006) have published the first randomized controlled trial that compares conventional Pap testing to LBC in a screening population. Although LBC decreased the unsatisfactory Pap rate, its sensitivity was similar to that of conventional Pap tests, but with a lower positive predictive value. The deficiencies of comparative data, uncertainties of cost effectiveness, and potential adverse consequences of decreased specificity with LBC have been reviewed elsewhere (Davey, 2006; Sawaya, 1999; Spitzer, 1998).

SCREENING GUIDELINES

Current cervical cancer screening guidelines are more evidence-based and comprehensive than in the past. The three agencies offering guidelines are the American College of Obstetricians and Gynecologists, the American Cancer Society (ACA), and the U.S. Preventive Services Task Force (USPSTF) (Table 29-3) (American College of Obstetricians and Gynecologists, 2003; Saslow, 2002; U.S. Preventive Services Task Force, 2006).

Table 29-3 Cervical Cytology Screening Guidelines

	ACS	ACOG	USPSTF
Initiation of screening	Approximately 3 years after onset of vaginal intercourse; no later than age 21	See ACS	See ACS
Screening intervals for women at average risk	Age ≤30: annual if conventional smear; every 2 years if LBC test	Age ≤30: annual	At least every 3 years
	Age >30: every 2 to 3 years after 3 consecutive negative tests	Age >30: see ACS	
Screening intervals for women at higher risk	HIV + or other immunocompromised state: 2 tests during first year after immune disease diagnosis, then annually (per CDC)	HIV +: see ACS Other immunocompromised states, DES: may require more frequent screening	No specific recommendations
		History of CIN 2 or 3 or cervical cancer: annual	
Discontinuation of screening	Age 70: consider if 3 documented negative (and no abnormal) tests in prior 10 years	Age 70 in low-risk women	Age 65 if not otherwise at high risk for cervical cancer
	Continue if screening history uncertain, history of cervical cancer, DES, recent HPV +, HIV + status, other immunocompromised state	Continue if high risk, sexually active, history of multiple sexual partners, or history of abnormal cytology	
Screening after hysterectomy	Not indicated if removal confirmed for benign indication Subtotal hysterectomy: continue screening per guidelines	Not indicated if removal confirmed with benign pathology and past negative cytologies	Not recommended if total hysterectomy for benign disease
	Continue screening if history of DES or cervical cancer	See ACS	See ACS

	cervical cancer	Positive or uncertain history of CIN 2 or 3: annual screening until 3 negative tests obtained, then may discontinue	

ACOG = American College of Obstetricians and Gynecologists; ACS = American Cancer Society; CDC = Centers for Disease Control and Prevention; CIN = cervical intraepithelial neoplasia; DES = in utero diethylstilbestrol exposure; HIV+ = human immunodeficiency virus infection positivity; HPV+ = human papillomavirus DNA positivity; LBC = liquid-based cytology; USPSTF = U.S. Preventive Services Task Force.

Data from American College of Obstetricians and Gynecologists, 2003, Saslow, 2002, and U.S. Preventive Services Task Force, 2003, with permission.

Initiation of Screening

Cervical cancer does occur in adolescents, but it is rare. Accordingly, screening should begin approximately 3 years after coitarche or by age 21, whichever occurs first. Screening by age 21 regardless of sexual history protects those who are unwilling or unable to reveal sexual activity, whether consensual or resulting from abuse or assault. The 3-year window after coitarche recognizes that high-grade cervical neoplasia and cancer usually take several years to develop after exposure to HPV and avoids unnecessary detection of transient HPV infections and low-grade neoplastic lesions in adolescents (Moscicki, 1998). Earlier commencement of screening is acceptable at the discretion of the health care provider.

After age 30, women at average risk for cervical cancer can be screened at 2- to 3-year intervals if three consecutive, annual negative Pap tests have been documented. Women at higher risk due to prior treatment for CIN 2, CIN 3, or cervical cancer, in utero DES exposure, or immunosuppressive illness or medications should receive at least annual screening. Specifically, HIV-infected women require a Pap test twice during the first year after diagnosis and annually thereafter (Centers for Disease Control and Prevention, 2002).

These guidelines should not preclude or delay other indicated gynecologic care. Supplying contraception and other medical therapies should not be contingent upon compliance with cervical cancer screening recommendations or evaluation of cytologic abnormalities, especially for adolescents.

Discontinuation of Screening

Screening may be stopped at age 65 or 70 in women not at high risk for cervical cancer. Similarly, vaginal cancers are rare, accounting for less than 2 percent of cancers in women, and screening in most women who have undergone total hysterectomy for benign disease may be halted (Saraiya, 2001; Sirovich, 2004).

HPV TESTING FOR PRIMARY CERVICAL CANCER SCREENING

In 2003, the FDA approved the use of the Hybrid Capture 2 test for HR HPV in combination with cytology for cervical cancer screening in women aged 30 years and older. The combination of HPV DNA testing with cytology increases the sensitivity of a single Pap test for high-grade neoplasia from 50 to 85 percent, to nearly 100 percent (American College of Obstetricians and Gynecologists, 2005b). In women younger than 30 years, the high prevalence of HR HPV infection makes this strategy too nonspecific for use.

For primary screening, a cervical sample for HPV can be sent in a collection device separate from the cytology specimen. This allows simultaneous processing of the two components.

The increased sensitivity and acceptable specificity of HPV DNA testing combined with cervical cytology for women age 30 years and older eliminates the need for annual screening in this age group and is cost effective (Wright, 2004). If both tests are negative, they are not to be repeated in less than 3 years regardless of a history of new sexual partners. The chance of cervical cancer being present or developing during a 3-year screening period is extremely low, at approximately 1 in 1,000 (American College of Obstetricians and Gynecologists, 2005b, Wright, 2007a).

Evidence-based guidelines have been developed for management of an abnormal HPV DNA test plus cytology results (Wright,

2007a). If cytology is abnormal, current cytology management guidelines are followed (Epithelial Cell Abnormalities: Significance and Management). Cytology-negative and HPV-positive test results will occur in less than 7 percent of screened patients. In such cases, it is recommended that cytology and HPV DNA testing be repeated 12 months later. Colposcopy is recommended for persistently positive HPV DNA test results. An abnormal repeat cytology result is managed according to current guidelines.

THE 2001 BETHESDA SYSTEM

In 1988, standardization of cervical cytology reporting took place with the development of the Bethesda System nomenclature (National Cancer Institute Workshop, 1989). Subsequent revisions led to the 2001 Bethesda System for reporting cervical cytology results. Its components are seen in Table 29-4 (Solomon, 2002). Clinically, the key elements are assessment of specimen adequacy and epithelial cell abnormalities (Table 29-5).

Table 29-4 The 2001 Bethesda System Cytology Report Components
Specimen type
Conventional Pap test
Thin-layer liquid-based cytology
Specimen adequacy
Satisfactory for evaluation
Unsatisfactory for evaluation
General categorization (optional)
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormality
Other findings that may indicate increased risk
Interpretation of results
Negative for intraepithelial lesion or malignancy
Organisms:
Trichomonas vaginalis
Fungal organisms consistent with *Candida* species
Shift in flora suggestive of bacterial vaginosis
Cellular change consistent with herpes simplex virus
Bacteria consistent with *Actinomyces* species
Other non-neoplastic findings (optional)
Reactive cellular changes (inflammation, repair, radiation)
Glandular cells posthysterectomy

Atrophy
Epithelial cell abnormalities
Squamous cell
Glandular cell
Other:
Endometrial cells in a woman ≥40 years of age
Automated review and ancillary testing as appropriate
Educational notes and recommendations (optional)

Specimen Adequacy

Specimen adequacy is reported as satisfactory or unsatisfactory for evaluation, based primarily on criteria for slide cellularity and the presence of obscuring blood or inflammation. The presence of transformation zone (TZ) components (endocervical or squamous metaplastic cells or both) is evidence that the area at risk has been sampled, but is no longer requisite for adequacy. Notation is made as to their presence or absence. Their presence is associated with increased detection of cytologic abnormalities, but their absence is not reported to be associated with failure to diagnose CIN. Pap tests lacking TZ components or partially obscured by blood or inflammation should be repeated in 1 year or earlier if clinically indicated by individual risk factors and adequacy of past

screening (American College of Obstetricians and Gynecologists, 2003; Saslow, 2002). Rarely, obscuring blood and inflammation on cervical cytology indicate the presence of invasive cancer. Therefore, presence of an unexplained vaginal discharge, abnormal bleeding, or abnormal physical findings should prompt immediate evaluation rather than awaiting repeat Pap testing.

Epithelial Cell Abnormalities: Significance and Management

A cytology report is a medical consultation that interprets a screening test and is not a diagnosis. Thus, a final diagnosis is determined clinically, often with results from histologic evaluation.

Pap tests are interpreted as either negative for intraepithelial lesion or malignancy, or consistent with one or more epithelial cell abnormalities. To address abnormal findings, evidence-based management guidelines have been developed and are summarized in Table 29-6 (American College of Obstetricians and Gynecologists, 2005a; Wright, 2007a). Alternative management strategies may be appropriate based on individual patient characteristics, available resources, and other clinical factors.

Table 29-6 Cervical Cytology: Initial Management of Epithelial Cell Abnormalities

Epithelial Cell Abnormality	General Recommendation	Special Circumstances
ASC-US	Repeat cytology at 6 and 12 months Reflex HPV DNA testing Colposcopy	Refer to colposcopy for recurrent abnormal cytology, or initial positive HPV DNA test; adolescents[b] managed with repeat annual cytology
LSIL	Colposcopy for non-adolescent women	Adolescents managed with repeat annual cytology; HPV DNA test at 12 months or repeat cytology at 6 and 12 months are also acceptable for postmenopausal women
ASC-H, HSIL, squamous cell carcinoma	Colposcopy	
AGC, AIS, adenocarcinoma	Colposcopy, endocervical curettage[a] ; HPV DNA testing for AGC	Endometrial sampling[a] indicated if age >35 years, abnormal bleeding, chronic anovulation, or atypical endometrial cells specified

[a] Endocervical curettage and endometrial sampling are contraindicated in pregnancy.

[b] adolescents = age 13 to 20 years.

AGC = atypical glandular cells; AIS = adenocarcinoma in situ; ASC-H = atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion; ASC-US = atypical squamous cells of undetermined significance; HPV = human papillomavirus; HSIL = high-grade squamous intraepithelial lesion; LSIL = low-grade squamous intraepithelial lesion.

Adapted from Wright, 2007a, with permission.

Atypical Squamous Cells of Undetermined Significance

The most common cytologic abnormality is atypical squamous cells of undetermined significance (ASC-US), which indicates cells that are suggestive of, but do not fulfill the criteria for, SIL. Although an ASC-US result often precedes the diagnosis of CIN 2 or 3, this risk approximates only 5 percent and cancer is found in only 1 to 2 per thousand instances (Solomon, 2002). Therefore, the evaluation of ASC-US should not be overly aggressive, particularly in adolescents who are at low risk of cervical cancer (American College of Obstetricians and Gynecologists, 2006a; Moscicki, 2005).

Three options for evaluation of ASC-US are HPV DNA testing, colposcopy, or repeat cytologies at 6 and 12 months, with referral to colposcopy if either of these is abnormal (Wright, 2007a). If LBC is used, reflex HPV DNA testing from the same specimen is preferred. If high-risk HPV DNA types are found, colposcopy is indicated, as risk of CIN 2 or worse is equal to that of LSIL cytology.

If high-risk HPV DNA is absent, then a subsequent Pap test in 12 months is recommended. Alternatively, immediate colposcopy may be considered in certain patients, such as those who are unlikely to be compliant with further testing.

ASC-US cytologies are evaluated differently in adolescents age 20 years and younger due to a higher rate of HPV positivity, the rarity of cervical cancer, and the high rates of spontaneous regression of cervical neoplasia in this group. (Boardman, 2005; Wright, 2006). Reflex HPV testing should not be done. Instead, annual repeat cytology should be obtained and colposcopy performed only with a high-grade cytology result or if any cytologic abnormality persists at 2 years (Wright, 2007a).

Atypical Squamous Cells, Cannot Exclude HSIL

Five to 10 percent of ASC is designated as atypical squamous cells, cannot exclude high grade (ASC-H). This describes cellular changes that do not fulfill criteria for HSIL cytology, but for which a high-grade lesion cannot be excluded. Histologic HSIL is found in upwards of 25 percent of these cases. This is higher than that seen with ASC-US, and therefore colposcopy is indicated for evaluation (Wright, 2003, Wright 2007a).

Low-Grade Squamous Intraepithelial Lesion

This cytology result indicates the likely presence of HPV infection or low-grade neoplasia. Low-grade SIL encompasses the cytologic features of HPV infection and CIN 1 and carries a 15 to 30 percent risk of CIN 2 or 3, similar to the ASC-US HPV-positive category. Therefore, colposcopy is indicated for most. HPV testing is not useful in reproductive-aged women, as approximately 80 percent will test positive for HPV DNA (ALTS Group, 2000). Adolescents with LSIL should initially be managed with repeat cytology as with ASC-US. Due to a lower positive predictive value of LSIL cytology for CIN 2 or 3 and a lower rate of HPV positivity in postmenopausal women, alternative management of LSIL includes reflex HR HPV testing or repeat cytology at 6 and 12 months. HPV positivity or abnormal repeat cytology are indications for colposcopy.

High-Grade Squamous Intraepithelial Lesion and Glandular Abnormalities

High-grade SIL, all glandular epithelial cell abnormalities, and suspicion of carcinoma should all be evaluated by prompt colposcopic evaluation. High-grade SIL cytology encompasses features of CIN 2 and CIN 3 and carries a high risk of underlying histologic CIN 2 or CIN 3 (at least 70 percent), or invasive cancer (1 to 2 percent) (Kinney, 1998). Alternative management of HSIL cytology in women age 21 years and older includes immediate diagnostic loop excision because colposcopy may miss a high-grade lesion and most HSIL cytologies eventually result in excision for diagnosis or treatment. HPV DNA testing is not useful in the management of HSIL cytology.

As reviewed by Schnatz and associates (2006), squamous neoplasia is the most common diagnosis found upon evaluation of atypical glandular cell (AGC) cytology, but there is also a high risk of both endocervical and endometrial, as well as other reproductive tract cancers. Therefore, colposcopic evaluation of a glandular abnormality should include endocervical sampling in nonpregnant patients. Endometrial biopsy is indicated in women older than 35 years or in those younger if there is a history of abnormal bleeding, if risk factors for endometrial disease are noted, or if the cytology indicates that the atypical glandular cells are of endometrial origin.

If colposcopy and biopsies are without evidence of neoplasia, management of glandular abnormalities is generally more aggressive than for other abnormalities due to a higher risk of occult disease. Current consensus guidelines should be followed (Wright, 2007a). Surveillance may include post-colposcopy HPV testing, repeat cytologies, or excision, depending on the glandular abnormality and other clinical factors.

NON-NEOPLASTIC FINDINGS

Certain non-neoplastic findings may be reported, including findings consistent with, but not conclusively diagnostic of, certain organisms. These findings include *Trichomonas vaginalis, Candida* species, *Actinomyces* species, herpes simplex virus, or flora consistent with bacterial vaginosis. Confirmatory tests or clinical correlation should dictate any action related to these findings. Other non-neoplastic findings are reactive changes associated with inflammation or repair, radiation, changes, benign glandular cells posthysterectomy, and atrophy. None of these warrant a specific action on the part of the clinician.

Because the menstrual history of a woman is often unknown to the cytologist, endometrial cells that appear benign are reported on

Pap reports for all women aged 40 years and older. As reviewed by Browne and colleagues (2005), the need for evaluation in normally menstruating women has been controversial and therefore individualized according to clinical history and risk factors. The 2006 consensus guidelines recommend that no evaluation is needed in an asymptomatic premenopausal woman (Wright 2007a). However, postmenopausal women, and those with abnormal bleeding or the presence of other risk factors for endometrial disease should undergo further evaluation of the endometrium (see Chap. 8, Endometrial Biopsy).

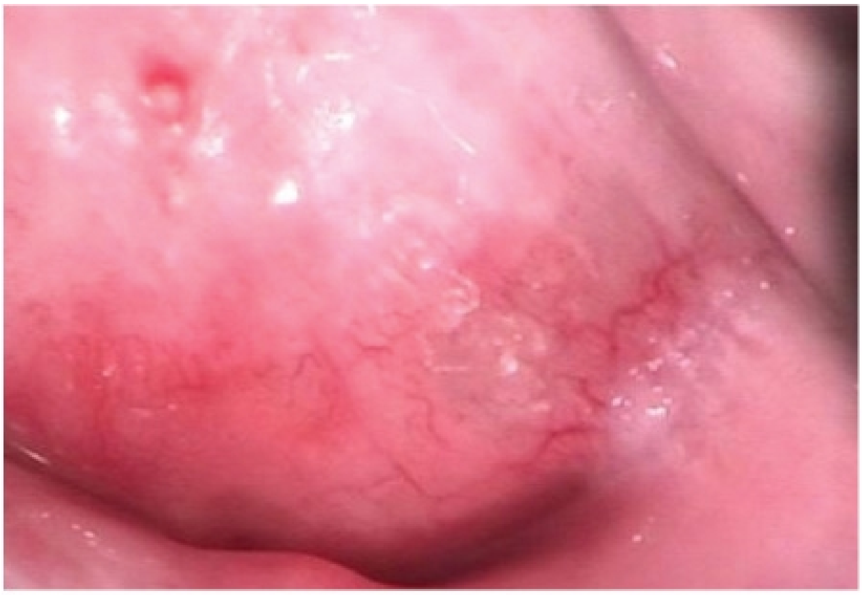
Colposcopy

Colposcopy is an outpatient procedure that is simple, quick, and well-tolerated. It allows examination of the lower genital tract and anus with a microscope to further evaluate abnormal Pap test results and visible epithelial abnormalities. This allows identification and management of premalignant lesions. Colposcopic examination of the cervix remains the clinical standard in the evaluation of patients with abnormal cervical cytology. However, its sensitivity, interobserver agreement, and reproducibility have recently come into question (Ferris, 2005).

COLPOSCOPE

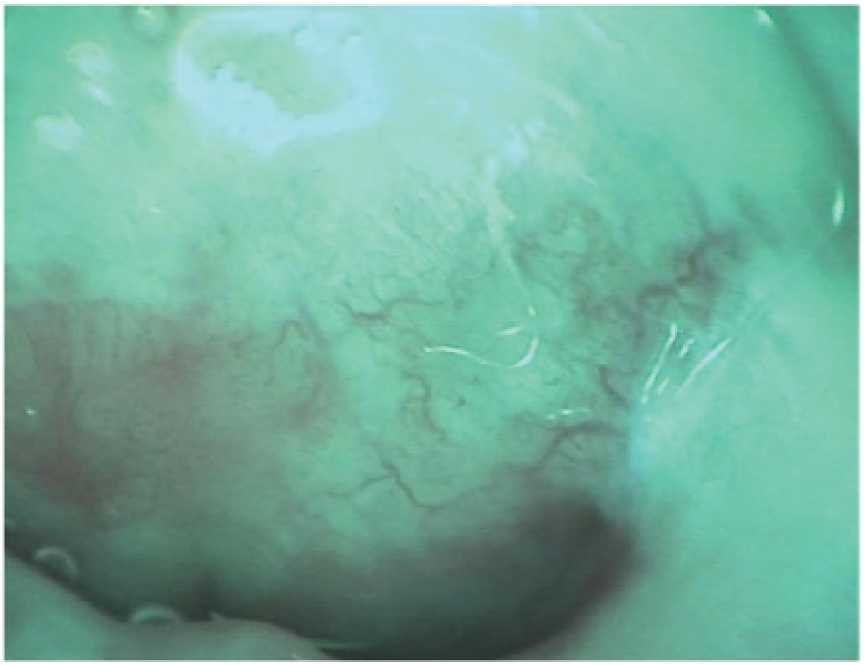
There are many styles of colposcopes, but they all operate similarly. The colposcope consists of a stereoscopic viewing system with magnification settings ranging from three- to 40-fold attached to a freely moveable stand. A high-intensity halogen light provides illumination. Use of a green (red-free) light filter emphasizes contrast by causing the color red to appear black, aiding the examination of vascular patterns (Fig. 29-6).

FIGURE 29-6



A

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com



A. Benign surface vessels viewed through a colposcope using usual white light source. **B.** Use of a blue-green (red-free) light filter provides higher contrast and definition of vascular patterns.

PREPARATION

Prior to colposcopic examination, a woman's medical record, including past gynecologic and dysplasia histories, should be reviewed and indications for colposcopy confirmed (Table 29-7) (Epithelial Cell Abnormalities: Significance and Management). Urine pregnancy testing is warranted for sexually active patients who may be pregnant. Colposcopic examination is optimally timed to avoid menses. However, it should be performed despite menstruation if a gross lesion suspicious for invasive cervical carcinoma is seen, if a patient is noncompliant, or if there is a history of abnormal bleeding that may be mistaken as menstrual bleeding.

Table 29-7 Clinical Considerations Directing Colposcopy

Clinical objectives
Provide a magnified view of the lower genital tract
Identify squamocolumnar junction of the cervix
Detect lesions suspicious for neoplasia
Direct biopsy of lesions
Monitor patients with a current or past history of lower genital tract neoplasia
Clinical indications
Grossly visible genital tract lesions
Abnormal cervical cytology
History of in utero diethylstilbestrol exposure
Contraindications
None
Relative contraindications
Anticoagulant therapy if patient requires biopsy
Upper or lower reproductive tract infection
Uncontrolled severe hypertension
Uncooperative or overly anxious patient

A Pap test at the time of colposcopy is of questionable value and should be performed on an individualized basis. A saline wet prep, cervical culture, and treatment of an identified pathogen may be indicated in cases of severe cervicitis before performing biopsies or endocervical curettage.

SOLUTIONS

Normal Saline

Saline helps remove cervical mucus and allows vascular and surface features of lesions to be initially assessed. Abnormal vessels, especially when viewed with green filtered light, may be more prominent without acetic acid application.

Acetic Acid

Also known as white table vinegar, acetic acid is a mucolytic agent that reversibly clumps nuclear chromatin causing lesions to assume various shades of white depending on the resultant degree of abnormal chromatin density. Applying 3- to 5-percent acetic acid to mucosal epithelium results in the *acetowhite* change characteristic of neoplastic lesions as well as some non-neoplastic conditions.

Lugol Solution

Lugol iodine solution stains mature squamous epithelial cells mahogany in estrogenized women due to high cellular glycogen content. Due to attenuated cellular differentiation, dysplastic cells have lower glycogen content and fail to fully stain, appearing

various shades of yellow (Fig. 29-7). Lugol solution should not be used in patients allergic to iodine, radiographic contrast, or shellfish. Lugol solution is particularly useful when abnormal tissue cannot be found using acetic acid alone, and to better define the limits of the transformation zone.

A. Cervix after application of acetic acid. Several areas of acetowhite change adjacent to the squamocolumnar junction are apparent. **B.** Same cervix after application of Lugol iodine solution. Non-staining of the lesions at the 10 to 11 o'clock positions is seen (**black arrow**) while there is partial iodine uptake of acetowhite areas along the posterior SCJ (**white arrow**).

COLPOSCOPIC GRADING

Colposcopists are trained to discriminate between normal and abnormal tissue for biopsy purposes. Several colposcopic grading systems that quantify various colposcopic signs have been developed to improve accuracy (Coppleson, 1993; Reid, 1985). Best known, the Reid Colposcopic Index (RCI) has a reported histologic correlation of 97 percent. The RCI is based upon four colposcopic lesion features: *peripheral margin, color, vascular patterns,* and *Lugol solution (iodine) staining.* Each category is scored from zero to two and the summation provides a numeric index which correlates with histology (Table 29-8).

Table 29-8 Reid Colposcopic Index			
Colposcopic Sign	**Zero Points**	**1 Point**	**2 Points**
Margin	Condylomatous Micropapillary Feathery Satellite lesions	Smooth Straight	Rolled Peeling Internal border
Color: acetowhitening	Shiny Snowy Translucent Transient	Duller white	Dull white Gray
Vessels	Fine patterns Uniform caliber and patterns	Absent	Coarse patterns Dilated with variable caliber and intercapillary distances
Iodine staining	Positive	Partial	Negative

Adapted from Reid, 1985, with permission.

Lesion Margins and Color

Following application of 3- to 5-percent acetic acid to mucosal epithelium, the color or degree of whiteness obtained, rapidity and duration of acetowhitening, and sharpness of lesion borders are observed. High-grade lesions demonstrate a more persistent, duller shade of white, whereas low-grade lesions are translucent or bright white and fade quickly. Low-grade lesions characteristically have feathery margins, whereas high-grade lesions have straighter, sharper outlines (Figs. 29-8 and 29-9). A lesion with an internal border, that is, a lesion within a lesion, is typically high-grade.

FIGURE 29-8

High-grade squamous intraepithelial lesion. CIN 3 lesion after 5-percent acetic acid application demonstrating large size, well-defined borders, off-white dull coloration, and coarse vascular pattern.

Lesion Vascular Patterns

The vascular patterns associated with abnormal epithelium include punctation, mosaicism, and atypical vessels. Punctate and mosaic patterns are graded on the basis of vessel caliber, intercapillary distance, and the uniformity of each of these. Fine punctation and mosaicism, which are created by narrow vessels and uniform intercapillary distances, typify low-grade lesions. A coarse pattern results from wider and more variable vessel diameter and spacing. This indicates higher-grade abnormalities, whereas mosaic "tiles" with a central punctation indicate carcinoma in situ (CIS). Atypical vessels are terminal vessels that are irregular in size, shape, course, and arrangement (Fig. 29-10). These should raise the suspicion of cancer.

FIGURE 29-10

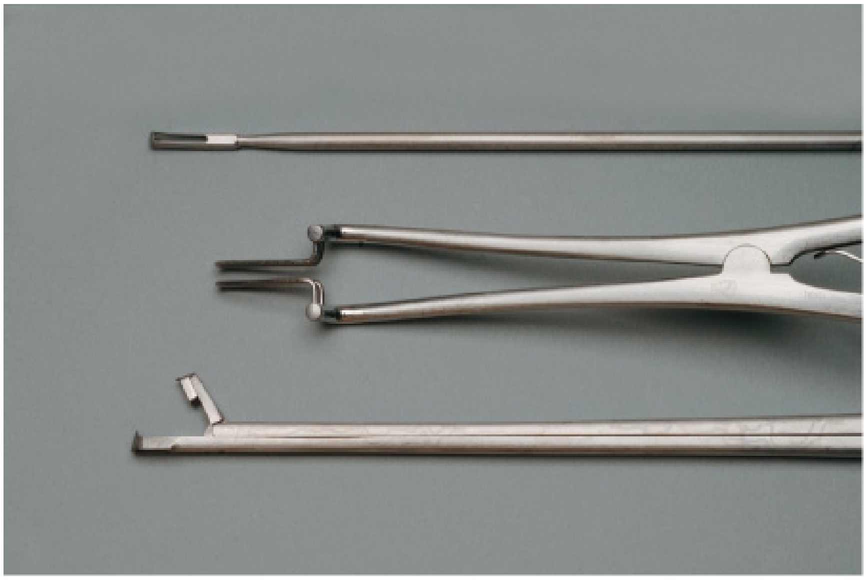
Mosaic vascular pattern with atypical vessels (**arrows**).

BIOPSY

Ectocervical Biopsy

Under direct colposcopic visualization, suspicious lesions on the ectocervix are biopsied using a sharp instrument such as a Tischler biopsy forceps (Fig. 29-11). Generally, cervical biopsy does not require an anesthetic. Thickened Monsel solution (ferric subsulfate) or a silver nitrate applicator, applied with pressure to the biopsy site, provides hemostasis. Extreme cases of bleeding are rare and can be controlled with vaginal packing.

FIGURE 29-11



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

From top to bottom, endocervical curette, endocervical speculum, and a cervical biopsy forceps.

Satisfactory Colposcopy

Within a neoplastic lesion, more severe disease tends to be at the proximal limit of the transformation zone. Thus, adequate visualization of the entire cervical SCJ and upper limits of all lesions defines whether a colposcopic examination is termed *satisfactory* or *unsatisfactory.* This determination can affect management. Therefore, with initially unsatisfactory colposcopy, an endocervical speculum may be used to dilate and fully visualize lesions that have extended cephalad into the endocervical canal (Fig. 29-12).

FIGURE 29-12

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Use of an endocervical speculum to visualize the endocervical canal during colposcopy.

Endocervical Curettage

For nonpregnant patients, endocervical curettage (ECC) is used to evaluate tissue within the endocervical canal not visualized by colposcopy. A normal ECC provides an added degree of assurance that a neoplastic endocervical lesion is not present (Grainger, 1987). Despite its common use, there are no randomized trials supporting the performance of ECC routinely during colposcopy (Abu, 2005).

Endocervical curettage generally is performed at the time of colposcopic assessment of an abnormal Pap test if:

- Colposcopy is unsatisfactory, which is common in postmenopausal women (Dinh, 1989)
- Atypical glandular cell cytology is evaluated (Granai, 1985; Wright, 2007a)
- Ablative treatment is planned (Husseinzadeh, 1989)
- Conization for adenocarcinoma in situ has been performed. During surveillance of these women, Schorge and associates (2003) found that negative ECC results may postpone repeat conization or definitive hysterectomy in women wanting to preserve fertility.

Endocervical curettage is performed by introducing an endocervical curette 1 to 2 cm into the cervical canal (see Fig. 29-11). The entire length and circumference of the canal is firmly curetted, carefully avoiding sampling of the ectocervix or lower uterine segment. Endocervical scrapings admix with cervical mucus, which may be removed using ring forceps or a cytobrush and included with the curettage specimen. Alternatively, a cytobrush may be used to obtain an endocervical tissue specimen.

Management of Histologic Cervical Intraepithelial Neoplasia

Management of CIN falls into two general categories: observation and treatment. The objective of all treatment is surgical obliteration of the entire cervical transformation zone, including abnormal tissue. This may be done by use of ablation, that is, tissue destruction with cryosurgery or laser ablation, or by excision of tissue. Excisional modalities include laser conization, cold-knife conization, and electrosurgical loop excision (Loop Electrosurgical Excision Procedure). All treatment modalities, particularly excisional procedures, are suspected of increasing the risk of adverse future reproductive outcomes, such as preterm delivery and premature rupture of membranes (Wright, 2007b).

Evidence-based consensus guidelines for the management of women with biopsy-confirmed CIN have been developed and recently updated through the organizational efforts of the American Society for Colposcopy and Cervical Pathology (Wright, 2003, 2007a). In general, histologic CIN 1 can be observed indefinitely, especially in adolescents, or treated if it persists for at least 2 years. This is also the case for CIN 2 lesions in adolescents. However, CIN 2 in adult women and CIN 3 are treated by excision or ablation except in special circumstances. The "see and treat" approach in which loop excision is performed at initial colposcopy is an acceptable option for high-risk, adult patients who present with high-grade cytology and corresponding colposcopic abnormalities. A prospective study using this approach found that 84 percent of patients had CIN 2 or 3 within the excisional biopsy specimen (Numnum, 2005). In the case of unsatisfactory colposcopy and histologic CIN, a diagnostic excisional procedure is recommended to exclude the presence of occult high-grade CIN or invasive cancer.

Adenocarcinoma in situ (AIS) of the cervix, although uncommon, is increasing in incidence and typically diagnosed at a younger age (Krivak, 2001). Exclusion of invasive cancer and removal of all affected tissue remains the primary goal. Cold-knife conization is recommended to optimize specimen orientation, interpretation of histology, and preservation of margins (American College of Obstetricians and Gynecologists, 2005b). The risk of residual AIS is reported to be as high as 80 percent in patients with positive margins and therefore, repeat conization is advisable (Krivak, 2001). Even with negative conization specimen margins and endocervical curettage, there is risk of residual disease. Therefore, hysterectomy is recommended after childbearing is completed (Krivak, 2001; Poynor, 1995).

When colposcopic and histologic evaluation fail to reveal the presence of high-grade neoplasia, further surveillance is recommended based upon the original abnormal cytology result as listed in Table 29-9. Guidelines are available for the management of abnormal cytology and cervical neoplasia during pregnancy with treatment of persistent disease postpartum (Wright, 2007b).

Table 29-9 Surveillance of Abnormal Cervical Cytology in the Absence of Histologic High-Grade Neoplasia

Cytology	Colposcopy/Histology	Recommended Follow-Up
ASC-US, HPV status unknown	No CIN found	Repeat cytology at 12 months
ASC-US, HPV + or LSIL	No CIN found	Cytology at 6 and 12 months or HR HPV testing at 12 months
ASC-H	No CIN found	Cytology at 6 and 12 months or HR HPV testing at 12 months
HSIL	No CIN 2/CIN 3 found	Satisfactory colposcopy: review cytology and histology results and colposcopic findings or repeat colposcopy and cytology at 6 month intervals for 1 year or diagnostic excision; Unsatisfactory colposcopy: diagnostic excision
AGC	No CIN or glandular neoplasia	Repeat cytology at 6-month intervals for four times if HPV status unknown; If HPV negative, repeat cytology and HR HPV testing at 12 months; If HPV positive, repeat repeat cytology and HR HPV testing at 6 months
AGC, favor	No invasive carcinoma	Diagnostic excisional procedure

AIS	No invasive carcinoma	Diagnostic excisional procedure

AGC = atypical glandular cells; AIS = endocervical adenocarcinoma; ASC-H = atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion; ASC-US = atypical squamous cells of undetermined significance; CIN = cervical intraepithelial neoplasia; HR HPV = high risk human papillomavirus; HSIL = high-grade squamous intraepithelial lesion; LSIL = low-grade squamous intraepithelial lesion.

Modalities for the Treatment of Cervical Intraepithelial Neoplasia

Current treatment of CIN is limited to local ablative or excisional procedures. Whereas ablative procedures destroy cervical tissue, excisional methods provide histologic specimens that allow the evaluation of excision margins and assurance that invasive cancer is not present. Medical treatment using topical agents is currently investigational and not recognized as standard clinical practice. Selection of treatment modality depends on multiple factors including patient age, parity, desire for future fertility, size and severity of a lesion(s), contour of the cervix, prior treatment for CIN, and co-existing medical conditions such as immunocompromise. Most randomized clinical trials evaluating differences in treatment success are underpowered and no clear evidence shows any treatment technique to be superior (Martin-Hirsch, 2006; Mitchell, 1998). Most reports suggest surgical treatments have approximately a 90-percent success rate.

ABLATIVE TREATMENT MODALITIES

Before using ablative treatment modalities, there must be no indication of invasive cancer by cytologic or histologic evaluation or by colposcopic impression and no suspicion of glandular disease (Spitzer, 1998). Before ablative procedures, colposcopic examination should be deemed satisfactory, and cytologic and histologic results should be concordant. Ablative treatment modalities include cryosurgery, electrofulguration, and carbon dioxide (CO_2) laser.

Cryosurgery

Cryosurgery delivers a refrigerant gas, usually nitrous oxide, through flexible tubing to a metal probe which freezes tissue on contact (see Section 41-13, Treatment of Ectocervical Preinvasive Lesions). Cryonecrosis is achieved by crystallizing intracellular water. This treatment is appropriate for lesions associated with satisfactory colposcopic examination and with biopsy-proven squamous dysplasia limited to two quadrants of the cervix. Cryosurgery is generally not favored for the treatment of CIN 3 due to higher rates of disease persistence following treatment and lack of histologic specimen to exclude occult invasive cancer (Table 29-10) (Martin-Hirsch, 2006). Moreover, cryosurgery and other ablative techniques are not favored for HIV-positive women with CIN due to high failure rates.

Table 29-10 Cryosurgery: Clinical Characteristics

Advantages
Favorable safety profile
Outpatient procedure
No anesthetic requirements
Ease of procedure
Low-cost equipment with minimal maintenance
Bleeding complications rare
No proven adverse reproductive effects
Acceptable primary cure rate
Disadvantages
No tissue specimen for histopathology evaluation
Cannot treat lesions with unfavorable sizes or shapes
Uterine cramping
Potential for vasovagal reaction
Profuse vaginal discharge postprocedure
Cephalad migration of squamocolumnar junction

Adapted from Martin-Hirsch, 2006, with permission.

Carbon Dioxide Laser

Treatment with *l* ight *a* mplification by *s* timulated *e* mission of *r* adiation, or *laser,* is delivered using colposcopic guidance with a micromanipulator. This modality vaporizes tissue to a depth of 5 to 7 mm (see Section 41-13, Treatment of Ectocervical Preinvasive Lesions). Laser ablation is appropriate for biopsy-proven squamous intraepithelial lesions associated with a satisfactory colposcopic examination. The laser is well suited for large, irregularly shaped lesions of all grades.

EXCISIONAL TREATMENT MODALITIES

Lesions suspicious for invasive cancer and AIS of the cervix must undergo a diagnostic excisional procedure. In addition, excision is indicated for patients with unsatisfactory colposcopy with histologic CIN or unexplained high-grade or recurrent AGC cytology. It is also warranted in cases of cytologic versus biopsy discordance when histologic results are significantly less severe. Excision is recommended for any posttreatment recurrence of high-grade CIN to allow complete histologic evaluation of the specimen (Singer, 1994). Women with recurrent CIN have a higher risk for occult invasive cancer (Paraskevaidis, 1991). Excisional treatment modalities include loop electrosurgical excision procedure (LEEP), cold-knife conization (CKC), and laser conization.

Excisional and perhaps ablative procedures are associated with operative and long-term operative risks including cervical stenosis, cervical incompetence, plus preterm birth as described by Jakobsson (2007). Furthermore, Himes (2007) suggests women with a shorter conization-to-pregnancy interval, that is, less than two to three months are at particular increased risk for preterm birth.

Loop Electrosurgical Excision Procedure

This technique uses a thin wire on an insulated handle through which an electrical current is passed. This creates an instrument that simultaneously cuts and coagulates tissue under direct colposcopic visualization (see Section 41-13, Treatment of Ectocervical Preinvasive Lesions). Because LEEP can be performed using local anesthesia, it has become the primary outpatient treatment modality for high-grade cervical lesions including those that extend into the endocervical canal (Table 29-11). LEEP provides a tissue specimen with margins that can be histologically evaluated to assure complete lesion removal. Additionally, the size and shape of tissue excision can be customized by varying loop type and the sequential order in which loops are used. This helps conserve cervical stroma volume.

Table 29-11 Loop Electrosurgical Excision Procedure: Clinical Characteristics
Advantages
Favorable safety profile
Ease of procedure
Outpatient procedure using local anesthesia
Low costs of equipment
Tissue specimen for histopathology evaluation
Disadvantages
Thermal damage may obscure specimen margin status
Special training required
Risk of postprocedure bleeding
Theoretical risk of vapor plume inhalation

Cold-Knife Conization

This surgical procedure removes the entire cervical transformation zone including the cervical lesion by scalpel (see Section 41-14, Cervical Conization). It is performed in an operating room and requires general or regional anesthesia (Table 29-12). Cold-knife conization is preferred for cases of unsatisfactory colposcopy, particularly with high-grade CIN extending deep into the endocervical canal, with endocervical glandular disease, and with some posttreatment CIN recurrences. Patient selection favors those at highest risk for invasive cancer including cervical cytology suspicious for invasive cancer, patients older than 35 years with CIN 3 or CIS, large high-grade lesions, and biopsies showing AIS.

Table 29-12 Cold-Knife Conization Clinical Characteristics
Advantages
Anesthetized patient
Tissue specimen for histopathology without margin compromise
Enhanced patient support if hemorrhage is encountered
Variety of instruments to individualize conization
Disadvantages
Potential for hemorrhage
Lengthier procedure
Postoperative discomfort
General or regional anesthesia required
Operating room setting
High cost
Larger volume of cervical stroma removed
Increased risk of adverse reproductive outcomes

Carbon Dioxide Laser Conization

This method has the disadvantages of expense and some thermal compromise of margins, but the advantages of less blood loss and precise cone size and shape tailoring. Requiring special training, this procedure can be performed under local or general anesthesia.

Further Cytologic and Colposcopic Surveillance

Posttreatment, additional patient surveillance is required (Wright, 2007b). Patients with excision margins negative for CIN or who have undergone an ablative procedure may be followed with cytology testing alone or with colposcopy every 6 months until two negative evaluations are obtained before returning to routine screening. Alternatively, HPV DNA testing may be done between 6 and 12 months post-treatment, and colposcopy performed for persistent HPV infection as this is a sensitive marker of disease persistence. Cytology screening should continue for at least 20 years thereafter due to a persistently increased risk of cervical neoplasia after a diagnosis of high-grade CIN. If excision margins or endocervical curettage done immediately after an excision are positive for CIN 2 or CIN 3, surveillance with repeat cytology and endocervical sampling 4 to 6 months later is preferred but repeat excision is also acceptable. Repeat diagnostic excision is indicated for special circumstances such as AIS or microinvasive carcinoma at the excision margins.

Hysterectomy

Hysterectomy is unacceptable as primary therapy for CIN 1, 2 or 3 (Wright, 2007b). However, it may be considered when treating recurrent high-grade cervical disease if childbearing has been completed or when a repeat cervical excision is strongly indicated but technically not feasible. Although hysterectomy provides the lowest recurrence rate for CIN, invasive cancer must always be excluded beforehand. The choice of either a vaginal or abdominal approach is directed by other clinical factors. Hysterectomy is the

preferred treatment of AIS when future fertility is not desired.

Even with negative cervical margins, hysterectomy performed for CIN is not completely protective. Patients, particularly those who are immunosuppressed, are at risk for recurrent disease and require postoperative interval cytologic screening of the vaginal cuff (Saslow, 2002).

VAGINAL PREINVASIVE LESIONS

Incidence

Vaginal cancer is rare, with a U.S. 2005 incidence of less than 2 percent of all gynecologic cancers (National Cancer Institute, 2006). Approximately 90 percent of vaginal cancers are squamous and develop slowly from precancerous epithelial changes, similar to CIN, called vaginal intraepithelial neoplasia (VaIN).

Pathophysiology

Vaginal intraepithelial neoplasia (VaIN) has histopathology similar to CIN and VIN, is rarely found as a primary lesion, and most often develops as an extension of CIN, mainly in the upper third of the vagina (Diakomanolis, 2002; Hoffman, 1992a). Unlike the cervix, the vagina lacks an active transformation zone susceptible to HPV-induced neoplasia. However, HPV entry may result from vaginal mucosal abrasions and reparative metaplastic squamous cell activity (Woodruff, 1981).

Risk Factors

Although the natural history of VaIN is less understood than that of CIN, risk factors for VaIN are thought to be similar to those for CIN, suggesting similar etiology (see Table 29-2). This disease is primarily found in postmenopausal women with an average age of 64 years (range 36 to 85 years) (Hoffman, 1992b). However, with recent increases in HPV infection of the LGT being seen in a younger population, VaIN is now being diagnosed in younger women. Cervical or vulvar neoplasia increases the risk for VaIN and vaginal squamous cancer.

Diagnosis

Generally, VaIN is asymptomatic. If present, symptoms may include vaginal bleeding, discharge, and odor. Abnormal cytology is most often the first indication of VaIN, particularly if the patient lacks a cervix. Integral to management, subsequent colposcopic examination of the lower genital tract frequently locates a vaginal lesion for biopsy.

VAGINAL COLPOSCOPY

Because of redundant vaginal tissue, vaginal colposcopy can be cumbersome. A clear plastic speculum may aid visualization of all quadrants of the vagina, with tissue in the upper third of the vaginal vault requiring particular attention. By applying 3- to 5-percent acetic acid to vaginal mucosa, acetowhite changes consistent with neoplasia are identified. Half-strength Lugol solution applied to the vagina delineates nonstaining areas, which are likely to contain abnormal epithelium. Biopsy may be obtained by means of a biopsy forceps and an Emmett hook to elevate and stabilize vaginal tissue. Local anesthesia is usually needed for biopsies of the lower half of the vagina. Hemostasis is achieved using silver nitrate applicators or Monsel paste. Vaginal lesion size, location, and specific biopsy sites are carefully documented for future management and surveillance.

Treatment of VaIN

Like high-grade CIN, high-grade VaIN is believed to be a precancerous lesion and requires eradication (Punnonen, 1989; Rome, 2000). Because vaginal neoplasia is uncommon, most management strategies are derived from small, nonrandomized, retrospective, and statistically under-powered investigations. Management of VaIN depends on the grade of neoplasia and may include observation, excision, ablation, topical antineoplastics, or rarely, radiation therapy. Each treatment method has advantages and disadvantages and none has proven to be of superior efficacy. Management strategies are determined by colposcopic and histologic findings along with comprehensive patient counseling.

LOW-GRADE VAGINAL INTRAEPITHELIAL NEOPLASIA (VAIN 1)

In a long-term study following 132 patients with VaIN, Rome and colleagues (2000) found that an observational approach after

biopsy resulted in regression in 7 of 8 patients (88 percent) with VaIN 1. Furthermore, no VaIN 1 lesion progressed to high-grade VaIN or invasive cancer. This lesion most likely represents atrophy or transient HPV infection.

HIGH-GRADE VAGINAL INTRAEPITHELIAL NEOPLASIA (VAIN 2 AND 3)

The treatment modality choice for patients with high-grade VaIN is influenced by the location and number of lesions, whether the patient is sexually active, vaginal length, previous radiation therapy, previous treatment modalities in patients with recurrent VaIN, and clinician experience.

Excision

Wide local excision of a high-grade unifocal lesion or partial vaginectomy for multifocal lesions may be used. Hoffman (1992a) found that 9 of 32 patients (28 percent) with prior hysterectomy and VaIN 3 had occult invasive cancer in the vaginal cuff. Therefore, surgical excision should be considered for high-grade lesions involving the region of a posthysterectomy vaginal cuff scar.

Excisional procedures have the advantage of providing a surgical specimen for which resected margins can be examined and the presence of invasive vaginal cancer excluded. Moreover, partial vaginectomy has the highest cure rate and fewest recurrences for high-grade disease (Dodge, 2001). Wide local excision carries less morbidity than vaginectomy, but both modalities may be complicated by bladder or rectal injury and hemorrhage. Subsequent vaginal scarring and stenosis may compromise vaginal intercourse or cause dyspareunia.

As an alternative excisional modality, CO_2 laser causes significant thermal damage to the tissue specimen and is not recommended. Likewise, LEEP has poor depth control and carries a substantial risk of thermal damage to underlying pelvic structures, including the bladder and bowel.

Medical Ablation

Before medical treatment, as with other ablative procedures, the possibility of invasive cancer must be excluded. Persistent VaIN 1 or 2 and selected VaIN 3 lesions may be medically treated using 5-percent fluorouracil (5-FU) cream off-label, as it is not FDA approved for this indication (Efudex, Valeant Pharmaceutical International, Costa Mesa, CA). A 3-mL dose of cream is placed in the vaginal vault by plastic vaginal applicator every other day for 3 days during the first week of treatment and once weekly thereafter for up to 10 weeks. This cream is often associated with a robust inflammatory reaction that can include vaginal burning and vulvar irritation. Because of this, the cream is best placed at night. An occlusive, water-resistant ointment can be used to protect the vulva and introitus.

Patients selected for this treatment require thorough counseling, effective contraception as needed, consent for off-label medication use, and close monitoring. Surveillance should include vaginal cytology and colposcopy 2 months after treatment is completed.

Carbon Dioxide Laser Ablation

Laser ablation is well-suited for eradication of multifocal lesions and causes less scarring and blood loss than excisional modalities. Rarely, excessive bleeding and thermal damage to the bladder and bowel can occur.

Radiation Therapy

There is a role for radiation treatment of high-grade VaIN, but it carries significant morbidity and should be reserved for select cases. In a review of 136 cases of vaginal carcinoma in situ, radiation therapy was used in 27 patients, with a 100-percent cure rate noted. However, 63 percent developed significant complications that included vaginal stenosis, adhesions, ulceration, necrosis, and fistula formation (Benedet, 1984). Furthermore, radiation treatment compromises subsequent cytologic, colposcopic, and histologic interpretation. Disease recurrence often necessitates radical surgery.

Prognosis

In a study of 132 patients with high-grade VaIN, excision and CO_2 laser ablation had similar cure rates of 69 percent. Topical 5-flurouracil cream was curative in 46 percent of cases (Rome, 2000). Patients with any grade of vaginal neoplasia require long-term monitoring, as the recurrence rate for high-grade disease is significant.

VULVAR PREINVASIVE LESIONS

Incidence

Vulvar cancer is rare, with a U.S. 2006 incidence of less than 3 to 5 percent of all gynecologic cancers and less than 0.5 percent of all cancers in women (National Cancer Institute, 2006). Ninety percent of vulvar cancer is squamous and in some cases develops slowly through precancerous epithelial changes called vulvar intraepithelial neoplasia (VIN). However, VIN is not necessarily analogous to CIN, as the vulva lacks a transformation zone, and VIN does not progress to high-grade disease and cancer as often.

A recent study identifying trends in the incidence of vulvar carcinoma in situ found a 411 percent increase from 1973 to 2000. This trend is particularly pronounced in younger women and is thought to be linked to the increased incidence of sexually transmitted infections (Howe, 2001).

Pathophysiology

Although HPV DNA has been found in 72 percent of VIN lesions, HPV is less commonly associated with vulvar cancer, with most studies showing approximately 40-percent HPV DNA positivity (Madeleine, 1997; Monk, 1995). The progression of vulvar carcinoma in situ to invasive cancer has been strongly suggested, although not confirmed conclusively. Therefore, VIN 3 lesions are generally treated (van Seters, 2005).

ORIGINAL TERMINOLOGY

Terminology for squamous VIN was introduced by the International Society for the Study of Vulvar Disease (ISSVD) in 1986. Under this classification, VIN grades 1, 2, and 3 were defined by abnormal cellular changes found to varying thickness within the squamous epithelium as in the case of CIN (Wilkinson, 1986).

NEW MODIFIED TERMINOLOGY

Classification of VIN has recently been simplified by the ISSVD (Sideri, 2005). The older designation of VIN 1 has been eliminated, whereas VIN 2 and 3 categories have been combined. This redefinition reflects whether lesions are likely to be premalignant or not, and therefore whether or not lesions require therapy. The VIN 1 category has been eliminated because evidence is lacking that such lesions are cancer precursors. These lesions more likely represent benign reactive or HPV effect. The term VIN is now applied only to histologically high-grade squamous cell lesions and combines the previous categories of VIN 2 and 3 (Table 29-13).

Table 29-13 Vulvar Intraepithelial Neoplasia: Terminology and Characteristics

VIN Type	**Clinical Presentation and Risk Factors**
VIN, usual type	Formerly VIN 2, VIN 3, vulvar CIS
Warty	Younger women
Basaloid	Multicentric disease
Mixed	Oncogenic HPV infection
	Smoking, other STIs, immunosuppression
VIN, differentiated type	2â€"10% of former VIN 3 lesions Older, postmenopausal women Oncogenic HPV infection uncommon
VIN, unclassified type	Rare pagetoid lesions

CIS = carcinoma in situ; HPV = human papillomavirus; STIs = sexually transmitted infections; VIN = vulvar intraepithelial neoplasia.

Vulvar intraepithelial neoplasia is now subcategorized into VIN, *usual type,* VIN, *differentiated type,* and VIN, *unclassified type.* Of these, VIN, usual type encompasses the former VIN 2 and 3 categories and clinically older dysplasia terms including carcinoma in situ. Lesions of VIN, usual type are associated with oncogenic HPV infection and can be grouped histologically as warty (condylomatous), basaloid, or mixed. In general, HPV DNA-positive high-grade VIN lesions morphologically resemble high-grade CIN and tend to be multifocal (Haefner, 1995).

The lower genital tract responds with a "field effect" to risk factors for cervical carcinoma, which may have similar influence on the squamous epithelia of the vulva and vagina (see Table 29-2). Accordingly, VIN, usual type is strongly associated with sexually transmissible infections and tobacco smoking, particularly in younger women (Hoffman, 1992b; Jones, 1994, 2005).

In contrast, VIN, differentiated type is less common and accounts for only 2 to 10 percent of all VIN 3 cases (Hart, 2001). This lesion is typically found in older, nonsmoking, postmenopausal women in their sixth and seventh decades. Infection with HPV is uncommon and probably does not play a role in the genesis of these lesions (Fig. 29-13).

A. Normal vulvar histology. *(Courtesy of Dr. Raheela Ashfaq.)* **B.** VIN 3 histology. *(Courtesy of Dr. Raheela Ashfaq.)*

Rare pagetoid types of VIN 2 and 3 that cannot be classified in any of the above categories are termed VIN, unclassified type (Sideri, 2005).

Diagnosis

Vulvar intraepithelial neoplasia may be asymptomatic and discovered during routine gynecologic examination or during evaluation of abnormal cervical or vaginal cytology. When present, signs and symptoms may affect a patient's sexuality and quality of life (Table 29-14).

Table 29-14 Symptoms of Vulvar Intraepithelial Neoplasia
Pruritus
Pain or burning
Vulvar soreness
Bleeding
Discharge
Urination discomfort
Persistent ulcer
Skin area that has a different color or texture from surrounding tissue
Existing nevus change in symmetry or color
Lump or wart-like growth

COLPOSCOPY

A histologic diagnosis is necessary before high-grade VIN is managed. This is best accomplished by magnification of the vulva and perianus, usually by use of a colposcope, or other means of simple magnification, with biopsy of the most abnormal-appearing areas.

Vulvar epithelial changes are enhanced by applying a 3- to 5-percent acetic acidâ€"soaked gauze pads to the vulva for 5 minutes prior to colposcopic examination. As an alternative, 1-percent toluidine blue may help define the best site for biopsy or the margins of surgical excision by staining abnormal nuclei (Joura, 1998). Procedurally, the vulva is painted with 1-percent toluidine blue, which is allowed to dry and then rinsed with 1-percent acetic acid. Toluidine blue is generally removed from normal tissue by the acetic acid rinse, whereas abnormal epithelium retains stain. Unfortunately, hyperkeratosis may give a false-negative result, and benign lesions or ulcers a false-positive test.

Vulvar intraepithelial neoplasia, usual type varies in clinical appearance. Some lesions are raised, hyperkeratotic, and pigmented (Fig. 29-14), whereas others are flat and white (Fig. 29-15). Often, lesions appear bulky, resemble condylomata, and are multifocal with extensive involvement of the perineum and adjacent skin.

Multifocal leukoplakia typical of high-grade VIN.

Vulvar intraepithelial neoplasia, differentiated type is generally unifocal and associated with lichen sclerosus or vulvar hyperplasia. A lesion may appear as an ulcer, warty papule, or hyperkeratotic plaque. Any lesion suspicious for invasive carcinoma should be biopsied, particularly lesions that are slightly elevated, roughened, nodular, or ulcerated. This is especially true in older women.

Adequate biopsies can be obtained by using a local anesthetic and biopsy punch up to 6 mm diameter (see Chap. 4, Vulvar Biopsy). If lesions are close to the clitoral hood, a general anesthetic is often warranted. Careful documentation and mapping of vulvar area biopsy sites will aid management plans.

Management

VULVAR INTRAEPITHELIAL NEOPLASIA 1

As previously stated, the progression of VIN 1 to VIN 3 has not been established and the modified 2004 ISSVD terminology has eliminated the VIN 1 category entirely. Lesions reported as VIN 1 may be reassessed annually and generally resolve without treatment.

VULVAR INTRAEPITHELIAL NEOPLASIA 2 AND 3

Because high-grade VIN is relatively rare, there are no sufficiently powered, long-term, randomized controlled studies investigating its management. Regardless of the modality selected, treatment side effects are common and can include vulvar discomfort, poor wound healing, infection, and scarring that may result in chronic dyspareunia. Treatment objectives should include: (1) improving patient symptoms, (2) preserving the appearance and function of the vulva, and (3) excluding invasive disease.

Standard treatment of high-grade lesions of the vulva can be achieved by local destruction or excision. Medical management with topical immune modulators or systemic agents is currently investigational. Treatment of VIN 2 or 3 is individualized and based on lesion location, size, and clinician expertise. Many patients are best treated by combined excisional and ablative procedures.

Excisional Surgery

Extensive vulvar surgery for VIN is not always necessary if patients undergo close monitoring for disease progression or recurrence. Carcinoma in situ or large lesions in which invasive carcinoma cannot be excluded by simple biopsy are best managed by wide local excision (WLE) with a surgical margin that includes at least 5 mm of normal tissue (see Sections 41-15, Wide Local Excision of Vulvar Intraepithelial Neoplasia and 43-25, Skinning Vulvectomy). Because disease recurrence is related to surgical margin status, frozen section histology of the specimen margins should be evaluated intraoperatively (Friedrich, 1980; Jones, 2005). Hopkins (2001) reported disease recurrence rates of 20 percent and 40 percent for negative and positive surgical margins, respectively.

Wide local excision may require skin grafting and can be disfiguring. All vulvar surgeries require thorough preoperative counseling regarding expected anatomic results and sexual function.

Ablative Treatment

Although providing good cosmetic results, lesion ablation with CO_2 laser does not allow histologic evaluation of a surgical specimen. Therefore, the presence of invasive carcinoma must be excluded beforehand. Although generally less disfiguring than WLE, laser ablation can result in prolonged and painful healing and in prolonged wound discharge. Preoperative counseling regarding anticipated postoperative results mirrors that for WLE. Recurrence of VIN has been reported more commonly following laser vaporization than after WLE (Herod, 1996). However, Hoffman (1992b) reported that 15 of 18 patients (83 percent) with VIN 3 remained free of recurrent disease after CO_2 laser ablation.

Cavitational ultrasonic surgical aspiration (CUSA) may be used in the treatment of high-grade VIN confined solely to non-hair-bearing vulvar skin. Ultrasound is used to cause cavitation and disruption of affected tissue, which is then aspirated and collected (see Chap. 40, Cavitational Ultrasonic Surgical Aspiration). This technique provides the advantages of laser ablation with less scarring or pain and also provides a histologic specimen. However, the tissue specimen is severely fragmented during the process and lacks the diagnostic accuracy of surgically excised tissue for ruling out the presence of invasive cancer. Miller (2002) evaluated this procedure in 37 patients with VIN 2 or 3 and found an overall recurrence of 35 percent during a mean surveillance period of 33 months.

Involvement of the pilosebaceous units by VIN occurs in up to two thirds of cases, but rarely exceeds 2.5 mm in depth from the epidermal surface (Shatz, 1989). This is important for disease management, particularly if ablative procedures are considered.

Topical Treatment

Topical treatments are currently under investigation and have not yet become recommended clinical therapy. These agents include imiquimod 5-percent cream (Aldara, 3M, St. Paul, MN), cidofovir emulsion (Vistide, Gilead, Foster City, CA), and 5-percent fluorouracil cream.

Photodynamic therapy (PDT) using topical 5-aminolevulinic acid (5-ALA) has been used as tissue-conserving treatment for vulvar carcinoma in situ. Although PDT preserves tissue without scarring or disfigurement, it has a low response and high recurrence rate (Kurwa, 2000).

Prognosis and Prevention

There are accumulating case reports supporting the invasive potential of untreated, high-grade VIN (Jones, 2005). Jones reviewed the outcome of 113 patients with VIN 3 and found that seven of eight untreated patients progressed to vulvar cancer. In contrast, only 3.8 percent of treated patients progressed to invasive carcinoma (Jones, 1994). It is currently not possible to predict high-grade VIN lesion behavior. Regardless of the treatment modality chosen, recurrence is common, particularly in patients with multifocal disease and immunocompromise. Surveillance for persistent and recurrent LGT disease is advisable.

ANAL INTRAEPITHELIAL NEOPLASIA (AIN)

Incidence

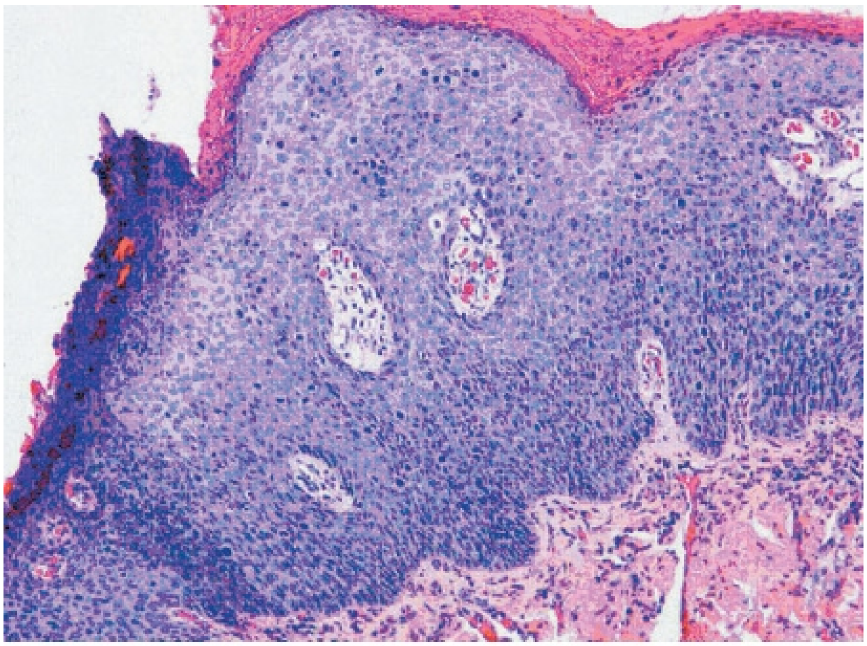
In the U.S., the incidence of anal cancer is increasing in both women and men (Melbye, 1994). Changes in sexual practices are likely partially responsible for this increase (Frisch, 1993). Anal cancer in women is strongly associated with sexually transmitted

infections including genital warts, infection with herpes simplex virus type 2, and infection with *Chlamydia trachomatis* (Daling, 1987).

Pathophysiology

As with cervical squamous cell cancers, oncogenic HPV types 16 and 18 are thought to be the principal etiologic agents responsible for the development of anal squamous cell cancers and their precursors (Zbar, 2002). Little is known of the natural history of anal HPV infection and its progressive potential in women, but it is suspected to behave similarly to cervicovaginal lesions. Cervical and anal lesions generally manifest adjacent to their respective squamocolumnar epithelial junctions, which in the anus is called the *transition zone* (Goldstone, 2001). Anal disease is classified by the same cytologic and histologic nomenclature used to describe cervical disease. Anal intraepithelial neoplasia (AIN) 1, 2, and 3 correspond to mild, moderate, and severe dysplasia, respectively (Fig. 29-16). Although not scientifically established, eradication of high-grade anal lesions may decrease the incidence of invasive cancer (Williams, 1994).

FIGURE 29-16



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

AIN 3 histology. *(Courtesy of Dr. Raheela Ashfaq.)*

Risk Factors

Risk factors for anal HPV lesions include anal receptive sexual activity, history of other sexually transmitted infections, immunosuppression, and tobacco smoking. Anal cancer and its likely precursor AIN 3 are increasing at higher rates in HIV-positive compared with HIV-negative patients (Frisch, 2000).

Diagnosis

SCREENING RECOMMENDATIONS

As with cervical cancer, prevention by screening persons at risk for abnormal anal cytology and treating high-grade anal lesions may be the best approach to decreasing the incidence of anal cancer (Berry, 2004; Friedlander, 2004; Palefsky, 1997). Specifically, some investigators believe annual anal cytology should be offered to all HIV-positive patients, but only if the infrastructure necessary to evaluate and manage abnormal cytology results and precancerous lesions is available (Palefsky, 2005; Panther,

2005). For the generalist who lacks adequate clinical resources and expertise to manage abnormal anal cytology, patients may be referred to tertiary care centers or colorectal surgeons for further evaluation and management. As a minimum, HIV-positive women with biopsy-proven LGT neoplasia should be provided a periodic digital examination of the anal canal.

ANAL CYTOLOGY

Anal cytology using liquid-based preparations is more sensitive than that from conventional glass slides (Friedlander, 2004; Sherman, 1995). Sampling is obtained by inserting a water-moistened Dacron swab or endocervical brush approximately 5 cm into the anal canal above the anal transition zone and then withdrawing the sampling device with a circular motion while applying pressure to the anal canal wall. The swab is then either swirled in the cytology solution to release exfoliated cells or smeared on a glass slide and fixed with isopropyl alcohol. Nothing per rectum is recommended 24 hours prior to an anal cytology test. Anal cytology is currently reported using Bethesda 2001 terminology for cervical cytology.

Management

The natural history of AIN in not yet established and all abnormal cytology requires high resolution anoscopy (HRA) evaluation. Anoscopy is performed using technique and terminology similar to cervical colposcopy as described by Jay and colleagues (1997) (Fig. 29-17).

Treatment

Treatment is restricted to locally ablative or excisional procedures that eliminate individual high-grade intraepithelial lesions. Unlike the cervix, the entire anal squamocolumnar junction cannot be destroyed or removed. Treatment of biopsy proven high-grade AIN lesions can be accomplished by a variety of ablative procedures including the carbon dioxide laser or electrocautery performed under general anesthesia, or with infrared coagulation (IRC) as an office procedure (Chang, 2002; Goldstone, 2005). Cryosurgery and topically applied 85-percent trichloroacetic acid are alternative treatment methods. Excision is indicated in cases where invasive cancer is suspected by cytology or examination.

THE HIV-INFECTED PATIENT

Pathophysiology

Human immunodeficiency virus (HIV)-infected women are known to have a high burden of HPV-associated anogenital disease. Recent studies show that HIV-positive women have a higher prevalence and longer persistence of cervical HPV infection (Palekfsky, 2003).

Additionally, studies consistently suggest HIV-positive women have much higher rates of CIN compared with HIV-negative women (Ellerbrock, 2000; Wright, 1994). For example, in women infected with HIV, up to 60 percent of Pap smears exhibit cytologic abnormalities, and as many as 40 percent have colposcopic evidence of dysplasia.

HIV infection influences LGT disease progression. For example, early during the AIDS epidemic, Maiman and colleagues (1990) observed that all HIV-positive women with cervical cancer died as a result of their cervical cancer, compared with only 37 percent of HIV-negative women. Because of this and related studies, cervical cancer was designated as an AIDS-defining condition by the Centers for Disease Control and Prevention and remains so (Ahdieh, 2001; Brown, 1994; Centers for Disease Control and Prevention, 2002; Palefsky, 1999).

Management

SCREENING

Because of a significantly higher risk of developing LGT neoplasia, cervical cytologic screening should be obtained every 6 months for the first year after an HIV infection diagnosis (Byrne, 1989; Centers for Disease Control and Prevention, 2006). Thereafter, annual screening for life is recommended. In addition, women with HIV may benefit from routine anal cytology screening (Palefsky, 2001).

ABNORMAL CYTOLOGY

Any cervical cytologic abnormality was formerly an indication for colposcopic evaluation. However, revised guidelines recommend that cervical cytologic abnormalities in immunocompromised women be evaluated similarly to the general population (Wright, 2007a). HIV-positive women with cervical intraepithelial neoplasia are often found to have dysplastic epithelial disease throughout the LGT (Hillemanns, 1996). Therefore, any indication for colposcopy warrants thorough evaluation of the entire lower genital tract.

Treatment

TREATMENT SELECTION

Ablative therapy is not recommended for HIV-positive women with high-grade cervical disease. Excisional procedures including loop excision, carbon dioxide laser, and cold-knife conization provide histology specimens for margin evaluation and assurance that invasive cancer is not present. Although excisional therapy is effective for eradicating CIN in immunocompetent patients, the same treatment seems to be effective only in preventing progression to cancer in HIV-infected women (Heard, 2005). Moreover, persistence and recurrence rates for excised LGT disease are higher in women with HIV compared with those without HIV infection.

HIGHLY ACTIVE ANTI-RETROVIRAL THERAPY

The therapeutic impact of these drugs on HPV infection is poorly understood and conflicting results have been reported (Heard, 2004). To date, highly active anti-retroviral therapy (HAART) has not been shown to consistently improve the natural history of HPV-related diseases. Indeed, if HAART leads to increased longevity yet does not alter the incidence or progression of HPV-related disease, individuals on HAART may have sufficient time to develop HPV-related epithelial cancers (de Sanjose, 2002).

CERVICAL CANCER: INTRODUCTION

Cervical cancer is the most common gynecologic cancer in women. Most of these cancers stem from infection with the human papillomavirus, although other host factors affect neoplastic progression following initial infection. Compared with other gynecologic malignancies, cervical cancer develops in a younger population of women. Thus, screening for this neoplasia with Pap smear sampling typically begins in adolescence or young adulthood.

Most early cancers are asymptomatic, whereas symptoms of advancing cervical cancer may include bleeding, watery discharge, and signs associated with venous, lymphatic, neural, or ureteral compression. Diagnosis of cervical cancer usually follows colposcopic examination and histologic evaluation of cervical biopsies.

This cancer is staged clinically, and stage is the most important indicator of long-term survival. Treatment varies and is typically dictated by this staging. In general, early stage disease is effectively eradicated surgically by either conization or radical hysterectomy. However, for those with advanced disease, chemoradiation is primarily selected. As expected, disease prognosis differs with tumor stage. Women with stage I disease typically have high survival and low recurrence rates, whereas those with advanced disease have a poorer long-term prognosis.

Prevention lies mainly in early detection. For this reason, regular Pap smear screening is recommended by the American College of Obstetricians and Gynecologists (2003) and by the U.S. Preventive Services Task Force (2003) (see Table 29-3).

INCIDENCE

Worldwide, cervical cancer is common, and ranks second among all malignancies for women (Parkin, 2005). In 2002, an estimated 493,000 new cases were identified globally and 274,000 deaths were recorded. In general, higher incidences are found in developing countries, and these countries contribute 83 percent of reported cases annually. Economically advantaged countries have significantly lower cervical cancer rates, and add only 3.6 percent of new cancers. This incidence disparity highlights successes achieved by cervical cancer screening programs in which Papanicolaou (Pap) smears are regularly obtained.

Within the United States, cervical cancer is the third most common gynecologic cancer and the sixth most common solid malignant neoplasm among women (Jemal, 2006). In the U.S., women have a 1 in 135 lifetime risk of developing this cancer. In 2006, the American Cancer Society estimated 9,710 new cases and 3,700 deaths from this malignancy (Parkin, 2005). Of U.S. women, African-Americans and women in lower socioeconomic groups have the highest age-standardized cervical cancer death rates from this cancer, and Hispanic and Latino women have the highest incidence rates (Table 30-1) (Jemal, 2006). This trend is thought to result mainly from financial and cultural characteristics affecting access to screening and treatment. The age at which cervical cancer develops is in general earlier than that of other gynecologic malignancies, and the median age at diagnosis ranges from 40 to 59 years. In women aged 20 to 39 years, cervical cancer is the second leading cause of cancer deaths.

Table 30-1 Cervical Cancer Age-Standardized Incidence and Death Rates						
	All Races	**White**	**African-American**	**Asian American and Pacific Islander**	**American Indian and Alaskan Native**	**Hispanic-Latino**
Incidence (%)	8.9	8.7	11.1	8.9	4.9	15.8
Death (%)	2.8	2.5	5.3	2.7	2.6	3.5

RISKS

In addition to demographic risks, behavioral risks have also been linked with cervical malignancy. Most cervical cancers originate from cells infected with the human papillomavirus (HPV), which is sexually transmitted. Early coitarche, multiple sexual partners, and increased parity are associated with a substantially greater incidence of cervical cancer (see Table 29-2). In addition, smokers are at greater risk, although the mechanism underlying this risk in not known.

The greatest risk for cervical cancer is the lack of regular Pap smear screening. Most communities that have adopted such screening have documented decreased incidences of this cancer (Jemal, 2006).

Human Papillomavirus Infection

It is now widely accepted that HPV is the primary etiologic infectious agent, and a detailed discussion of this virus is found in Chapter 29, Human Papillomavirus (Ley, 1991; Schiffman, 1993). Although other sexually transmitted factors, including herpes simplex virus 2, may play a concurrent causative role, 95 percent of cervical cancers are associated with an oncogenic HPV subtype (Brinton, 1992). For example, in a population-based study of HPV infection and cervical neoplasia, 80 percent of high-grade squamous intraepithelial lesions (HSIL) and invasive lesions were associated with HPV infection (Herrero, 2000). Specifically in this study, one half of HSIL and invasive cervical cancer cases were attributable to HPV serotype 16. Serotype 18 was associated with 15 percent of invasive disease. Moreover, recent trials show that vaccination against HPV-16 and HPV-18 reduces incident and persistent infections with 92-percent and 100-percent efficacy, respectively. However, the effective duration of these vaccines is not yet known.

LOWER SOCIOECONOMIC PREDICTORS

Lower educational attainment, older age, obesity, smoking, and neighborhood poverty are independently related to lower rates of cervical cancer screening. Specifically, those living in impoverished neighborhoods have limited access to screening and may benefit from outreach programs that increase Pap smear screening availability (Datta, 2006).

CIGARETTE SMOKING

Both active and passive cigarette smoking increases the risk of cervical cancer. Among HPV-infected women, current and former smokers have a two- to threefold increased incidence of HSIL or invasive cancer. Passive smoking is also associated with increased risk, but to a lesser extent (Trimble, 2005). Of cervical cancer types, current smoking has been associated with a significantly increased rate of squamous cell carcinoma, but not of adenocarcinoma. Interestingly, squamous cell and adenocarcinomas of the cervix share most risk factors with this exception of smoking. Although the mechanism underlying the association between smoking and cervical cancer is unclear, smoking may alter HPV infection in those who smoke. For example, "ever smoking" has been associated with reduced clearance of high-risk HPV (Koshiol, 2006; Plummer, 2003).

Reproductive Behavior

Parity and combination oral contraceptive (COC) pill use has a significant association with cervical cancer. Pooled data from case-control studies indicate that high parity increases the risk of developing cervical cancer. Specifically, women with seven prior full-term pregnancies have an approximately fourfold risk, and those with one or two have a twofold risk compared with nulliparas

(Munoz, 2002).

In addition, long-term COC pill use may be a cofactor. There is a significant positive correlation between a low serum estradiol:progesterone ratio and shorter overall cervical cancer survival in premenopausal women (Hellberg, 2005). In vitro studies suggest that hormones might have a permissive effect for the growth of cervical cancer, by promoting cell proliferation and thus allowing cells to be vulnerable to mutations. In addition, estrogen acts as an anti-apoptotic agent permitting proliferation of cells infected with oncogenic HPV. In women who are positive for cervical HPV DNA and who use COCs, risks of cervical carcinoma increase by up to fourfold compared with women who are HPV-positive and never users of COCs (Moreno, 2002). Additionally, current COC users and women who are within 9 years of use have a significantly higher risk of developing both squamous cell and adenocarcinoma of the cervix (Berrington, 2007).

Sexual Activity

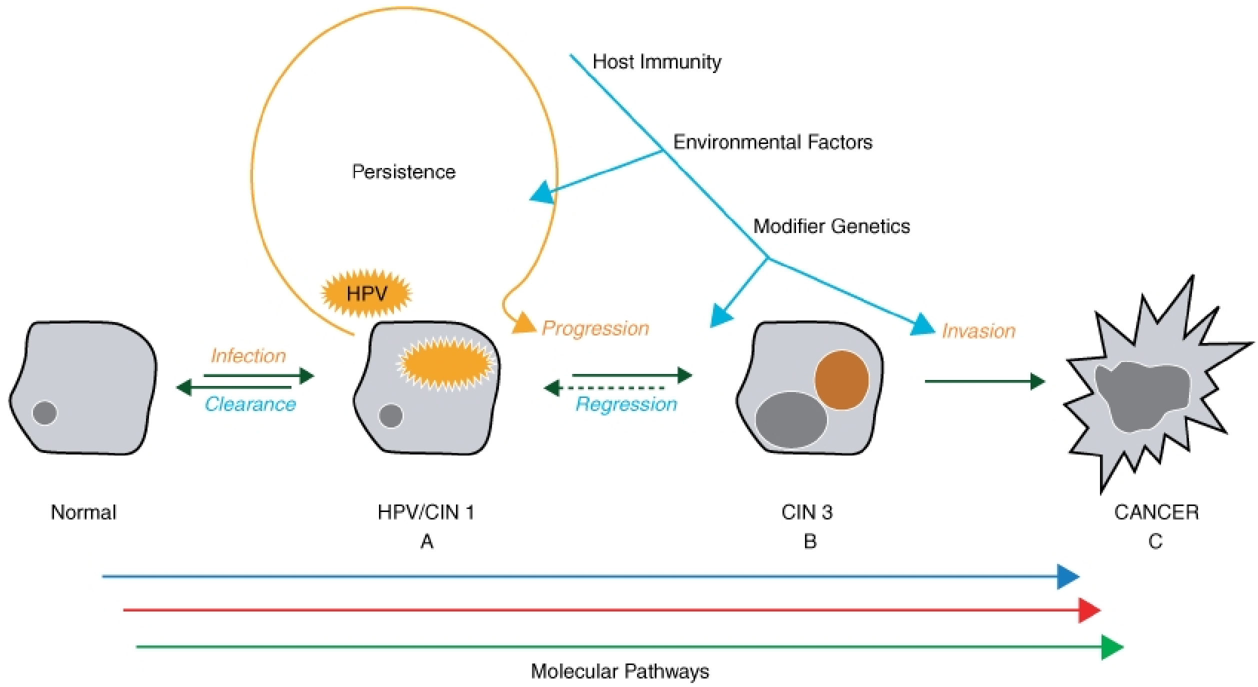
An increased number of sexual partners and early age of first intercourse have been shown to increase cervical cancer risks. Having more than six lifetime sexual partners imposes a significant increase in the relative risk of cervical cancer (Berrington, 2007). Similarly, early age of first intercourse before age 20 confers an increased risk of developing cervical cancer, whereas intercourse after age 21 only shows a trend towards an increased risk. Moreover, abstinence from sexual activity and barrier protection during sexual intercourse have been demonstrated to decrease cervical cancer incidence (Berrington, 2007).

PATHOPHYSIOLOGY

Tumorigenesis

Squamous cell carcinoma of the cervix typically arises at the squamocolumnar junction from a pre-existing dysplastic lesion, which in most cases follows infection with HPV (see Chap. 29, Outcome of HPV Infection) (Bosch, 2002). Although most women readily clear this virus, those with persistent infection may develop preinvasive dysplastic cervical disease (Fig. 30-1). In general, progression from dysplasia to invasive cancer requires several years, but wide variation exists. The molecular alterations involved with cervical carcinogenesis are complex and not fully understood. Uncovering these additional common molecular events has been difficult, and studies demonstrate vast heterogeneity. Accordingly, carcinogenesis is suspected to result from the interactive effects between environmental insults, host immunity, and somatic cell genomic variations (Helt, 2002; Jones, 1997, 2006; Wentzensen, 2004).

FIGURE 30-1



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Diagram illustrating genesis of cervical cancers. There are two critical endpoints on the spectrum of cervical dysplasia. **A.** This initial point represents the cell at risk due to active HPV infection. **B.** The clinically relevant preinvasive lesion, cervical intraepithelial neoplasia 3 (CIN 3) or carcinoma in situ (CIS) represents an intermediate stage in cervical cancer development. **C.** Interactive effects between environmental insults, host immunity, and somatic cell genomic variations lead to invasive cervical cancer.

Human papillomavirus plays a major role in the development of cervical cancers. Also increasing evidence suggests that HPV oncoproteins may be a critical component of continued cancer cell proliferation (Mantovani, 1999; Munger, 2001). Unlike low-risk serotypes, oncogenic HPV serotypes can integrate into the human genome. As a result, with infection, oncogenic HPV's early replication proteins E1 and E2 enable the virus to replicate within cervical cells (see Fig. 29-3). These proteins are expressed in high levels early in HPV infection. They can lead to cytologic changes detected as low-grade squamous intraepithelial (LSIL) cytologic findings on Pap smears.

Amplification of viral replication and subsequent transformation of normal cells into tumor cells may follow (Mantovani, 1999). Specifically, viral gene products E6 and E7 oncoproteins are implicated in this transformation (Fig. 30-2). E7 protein binds to the retinoblastoma (Rb) tumor suppressor protein, whereas E6 binds to the p53 tumor suppressor protein. In both instances, binding leads to degradation of these suppressor proteins. The E6 effect of p53 degradation is well studied and linked with the proliferation and immortalization of cervical cells (Jones, 1997, 2006; Mantovani, 1999; Munger, 2001). Other mechanisms of genetic alterations and molecular changes that occur in precancerous and cancerous cervical cancer cells are outlined in Tables 30-2 and 30-3.

FIGURE 30-2

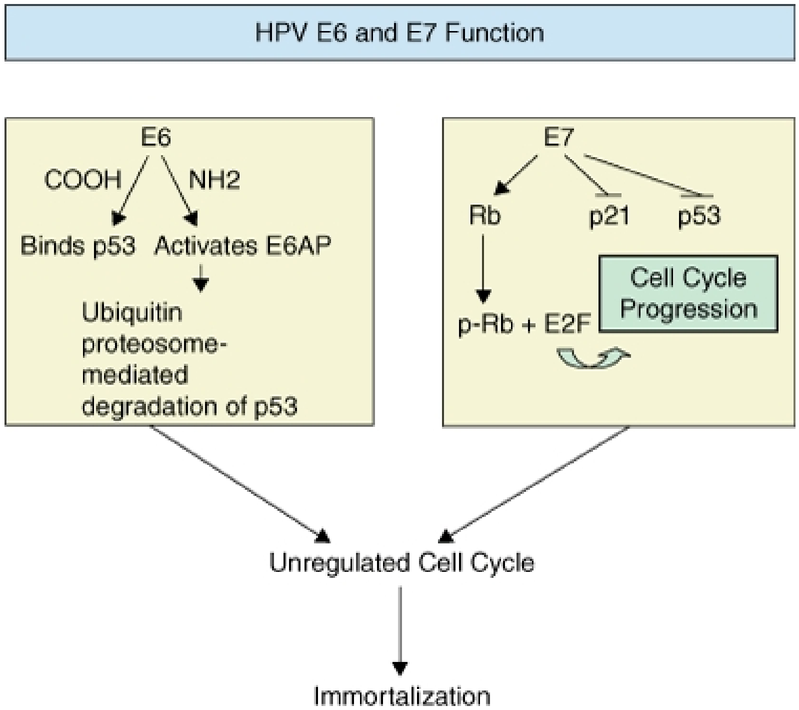


Diagram of E6 and E7 oncoproteins and p53, p21, and retinoblastoma (Rb) tumor suppressor proteins. On the left, viral oncoprotein E6 directly binds p53 and also activates E6AP to degrade p53 tumor suppressor protein. On the right, E7 oncoprotein phosphorylates retinoblastoma tumor suppressor protein resulting in release of E2F transcription factors, which are involved in cell cycle progression. E7 has also been shown to downregulate p21 tumor suppressor protein production and to subvert p53 function. The cumulative effect of oncoproteins E6 and E7 eventually result in cell cycle alteration, promoting uncontrolled cell proliferation.

Table 30-2 Genetic Alterations in Cervical Cancer

Genetic Alterations	**Mechanism**	**Function**
Overexpression of HPV E6 and E7 oncoproteins	Integration into host genome	Cell cycle deregulation; inhibition of apoptosis
Chromosomal aberrations	Regional gains and losses and global aneuploidy	Loss or gain of gene function
Epigenetic modification	Aberrant methylation	Loss of gene function

HPV = human papillomavirus.

Table 30-3 Molecular Predictors in Cervical Cancer		
Molecular Predictor	**Function**	**Expression and Impact on Prognosis**
Cyclin D1	Cell cycle regulation	Decreased expression in CIN, increased expression in cancers
P16	Cell cycle regulation	Overexpressed in dysplasias and cervical cancers
PTEN	Candidate TSG	Epigenetic changes and loss of gene expression in cervical cancers Gene mutations indicative of advanced-stage disease
cIAP1	Suppression of apoptosis	Overexpression in cancer cells is an independent predictor of DFS
COX-2	Induces cyclooxygenase activity	Overexpressed in CIN 3 Overexpression in cancers associated with decreased overall survival
EGFR	Tyrosine kinase receptor	Overexpression is associated with lower DFS when associated with overexpression with COX-2
HLA	HLA*A201, HLA-B7, and DQB1*0302	Altered host immune response

cIAP1 = cellular inhibitor of apoptosis protein 1; CIN = cervical intraepithelial neoplasia; COX-2 = cyclooxygenase-2; DFS = disease-free survival; EGFR = epidermal growth factor receptor; HLA = human leukocyte antigen; PTEN = phosphatase and tensin homologue deleted on chromosome 10; TSG = tumor suppressor gene.

Tumor Spread

Following tumorigenesis, the pattern of local growth may be exophytic if a cancer arises from the ectocervix, or may be endophytic if it arises from the endocervical canal (Fig. 30-3). Lesions lower in the canal are more likely to be clinically visible during physical examination. Alternatively, growth may be infiltrative, and in these cases ulcerative lesions are common if necrosis accompanies this growth.

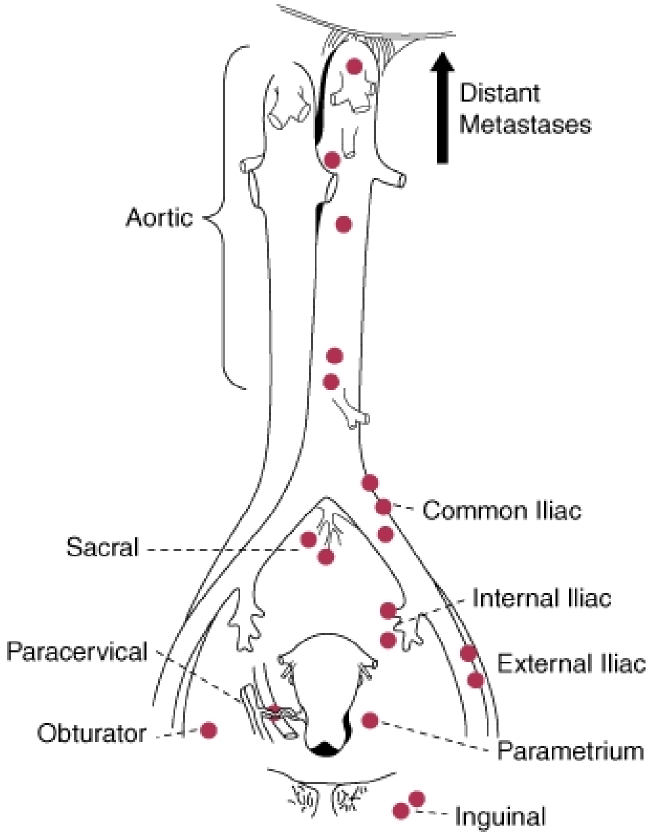
LYMPHATIC SPREAD

Lymph Node Groups

The cervix has a rich network of lymphatics, which follow the course of the uterine artery (Fig. 30-4). These channels drain principally into the paracervical and parametrial lymph nodes. Accordingly, these lymph nodes are clinically important and are removed as part of parametrial resection during radical hysterectomy. The lymphatics passing through the cardinal ligament empty into the ureteric node, which lies just lateral to the junction of the uterine artery. Although some experts consider this lymph node as distinct, others include this node within the paracervical nodal group.

FIGURE 30-4



Drawing of lymphatic drainage of the cervix. *(Redrawn from Henriksen, 1949, with permission.)*

From the parametrial and paracervical nodes, lymph subsequently flows into the obturator lymph nodes and into the internal, external, and common iliac lymph nodes. In contrast, lymphatic channels from the posterior cervix course through the rectal pillars and the uterosacral ligaments to the rectal lymph nodes. These nodes are encountered during radical hysterectomy and removed with the uterosacral ligaments.

The pattern of tumor spread typically follows cervical lymphatic drainage. Thus, lymphatics involving the cardinal ligaments and anterior and posterior parametria are commonly involved. As primary lesions enlarge and lymphatic involvement progresses, local invasion increases and will eventually become extensive.

Lymphovascular Space Involvement

As tumor invades deeper into the stroma, it enters blood capillaries and lymphatic channels (Fig. 30-5). Termed *lymphovascular space involvement* (LVSI), this type of invasive growth is not included in the clinical staging of cervical cancer. However, its presence is regarded as a poor prognostic indicator, especially in early stage cervical cancers. Thus, the presence of LVSI often requires tailoring of the appropriate surgical procedure and adjuvant radiation treatment.

LOCAL TUMOR EXTENSION

With extension through the parametria to the pelvic sidewall, ureteral blockage frequently develops (Fig. 30-6). Additionally, the bladder may be invaded by direct tumor extension through the vesicouterine ligaments. The rectum is invaded less often because it is anatomically separated from cervix by the posterior cul-de-sac. Distant metastasis results from hematogenous dissemination, and the lungs, ovaries, liver, and bone are the most frequently affected organs.

HISTOLOGIC TYPES

Squamous Cell Carcinoma

The two most common histologic subtypes of cervical cancer are squamous cell and adenocarcinoma. Of these, squamous cell tumors predominate, comprise 85 percent of all cervical cancers, and arise from the ectocervix (Fig. 30-7). Over the past 30 years, there has been a decrease in the incidence of squamous cell cancers and an increase in the incidence of cervical adenocarcinomas. These changes may be attributed to an improved method of screening for early squamous lesions of the cervix and an increase in the prevalence of HPV (Vizcaino, 2000).

FIGURE 30-7

Evidence describing the prognosis of these two cell types is contradictory. For example, a randomized study of stage IB and IIA cervical cancer by Landoni and colleagues (1997) showed a statistically significant lower overall survival in those with adenocarcinoma compared with squamous cell carcinoma. However, the Gynecologic Oncology Group (GOG) in a subsequent study found that overall survival in women with stage IB squamous and adenocarcinomas of the cervix is similar (Look, 1996). Moreover, the 1998 International Federation of Obstetricians and Gynecologists (FIGO) annual report, which reported more than 10,000 squamous carcinomas and 1,138 adenocarcinomas, noted no difference in survival in stage I cancers. However, with advanced stage disease, evidence suggests that cervical adenocarcinomas (stage IIB to IVA) may portend a poorer overall survival risk compared with that of squamous cell carcinomas (Eifel, 1990; Lea, 2002).

Adenocarcinomas

Adenocarcinomas are a group of cervical cancers comprised of the subtypes listed in Table 30-4. In contrast to squamous cell cervical carcinoma, adenocarcinomas comprise 10 to 15 percent of cervical cancers and arise from the endocervical mucus-producing glandular cells. Because of this origin within the endocervix, adenocarcinomas are often occult and may be advanced before becoming clinically evident.

Table 30-4 Histologic Subtypes of Cervical Cancer	
Squamous	
Adenocarcinoma	Endocervical type adenocarcinomas
	Endometrioid adenocarcinomas
	Minimal deviation adenocarcinoma
	Papillary villoglandular adenocarcinoma
	Serous adenocarcinoma
	Clear cell adenocarcinoma
	Mesonephric adenocarcinoma
Mixed cervical carcinomas	Adenosquamous carcinoma
	Glassy cell carcinoma
	Adenoid cystic carcinoma
	Adenoid basal epithelioma
Neuroendocrine tumors of the cervix	Large cell neuroendocrine
	Small cell carcinoma
Other malignant tumors	Sarcomas of the cervix
	Malignant lymphomas

Adenocarcinomas exhibit a variety of histologic patterns composed of diverse cell types. Of these, *mucinous endocervical adenocarcinomas* are the most common (Fig. 30-8). *Endometrioid adenocarcinomas* are the second most frequently identified and display glands resembling those of the endometrium. *Minimal deviation adenocarcinoma* is characterized by cytologically bland glands that are abnormal in size and shape. They contain an increased number of glands positioned at a deeper level than normal endocervical glands.

FIGURE 30-8

Mixed Cervical Carcinomas

These cervical malignancies are rare and histologically classified as adenosquamous, adenoid cystic, adenoid basal epithelioma, and glassy cell carcinoma. *Adenosquamous carcinomas* do not differ grossly from adenocarcinomas of the cervix. The squamous component is poorly differentiated and shows little keratinization. *Glassy cell carcinoma* describes a form of poorly differentiated adenocarcinoma in which cells display cytoplasm with a ground-glass appearance and a prominent nucleus with rounded nucleoli. *Adenoid cystic carcinoma* usually presents as a hard friable mass. Histologically this tumor resembles adenocarcinoma with adenocystic differentiation. Lastly, of this rare group of mixed tumors, *adenoid basal epitheliomas* typically behave in a benign fashion. Histologically, these tumors are characterized by nests and cords of small oval cells with a peripheral palisading arrangement.

Neuroendocrine Tumors of the Cervix

These malignancies include large cell and small cell tumors of the cervix. Large cell neuroendocrine tumors are highly aggressive and even early stage cancers have a relatively low disease-free survival rate despite treatment with radical hysterectomy and adjuvant chemotherapy (Albores-Saavedra, 1997). In contrast, small cell neuroendocrine carcinoma contains a uniform population of small cells with a high nuclear:cytoplasm ratio and resemble small cell carcinoma of the lung. Uncommonly, endocrine and paraendocrine tumors are associated with these neuroendocrine tumors.

Other Malignant Tumors

Rarely, the cervix may be the site of sarcomas and malignant lymphomas. Most of these tumors present as a bleeding cervical mass. Initially, differentiation of cervical sarcomas from primary uterine sarcoma requires careful pathologic examination and localization of the tumor's primary bulk. Cervical leiomyosarcomas and cervical stromal sarcomas have a poor prognosis, similar to uterine sarcomas (see Chap. 34, Leiomyosarcoma). Because these tumors are rare, statements regarding treatment of cervical

sarcomas are limited. Most cases are managed with multimodality treatment.

DIAGNOSIS

Symptoms

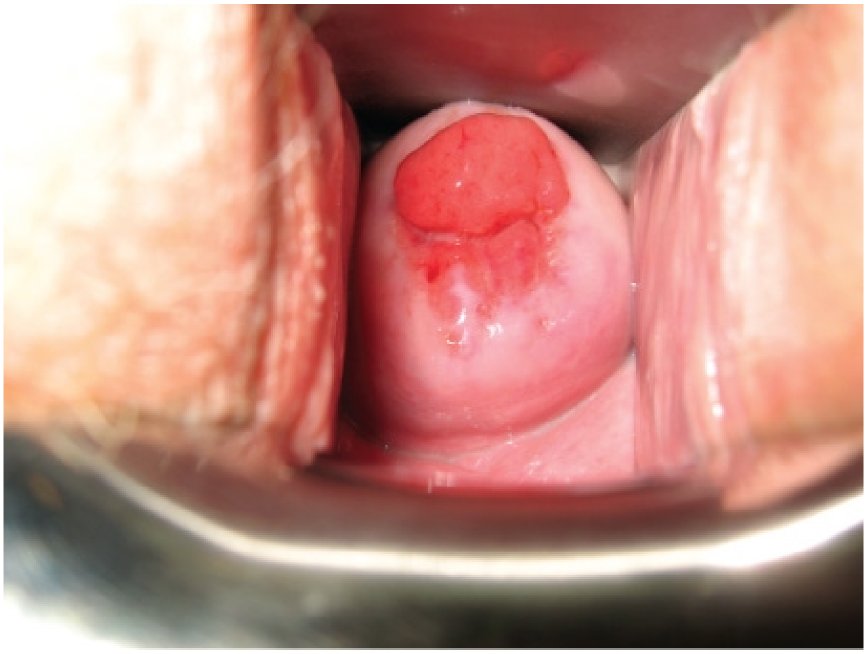
A large portion of women diagnosed with cervical cancer may be asymptomatic. For those with symptoms, however, early stage cervical cancer may create a watery, blood-tinged vaginal discharge. Intermittent vaginal bleeding that follows coitus or douching may also be noted. As a malignancy enlarges, bleeding typically intensifies and occasionally a woman may present to an emergency room with uncontrolled hemorrhage from a tumor bed. With parametrial invasion and extension to the pelvic sidewall, a tumor may compress adjacent organs to produce symptoms. For example, lower extremity edema and low back pain, often radiating down the posterior leg, may reflect compression of the sciatic nerve root, lymphatics, veins, or ureter by an expanding tumor. With ureteral obstruction, hydronephrosis and uremia can follow and may occasionally be initial presenting symptoms. Additionally, with tumor invasion into the bladder or rectum, women may note hematuria and/or symptoms of vesicovaginal or rectovaginal fistula.

Physical Examination

Most women with cervical cancer have normal general physical examination findings. However, with advancing disease, enlarged supraclavicular or inguinal lymphadenopathy, lower extremity edema, ascites, or decreased breath sounds with lung auscultation may indicate metastases.

In those with suspected cervical cancer, a thorough external genital and vaginal examination should be performed, looking for concomitant lesions. Human papillomavirus is a common risk factor for cervical, vaginal, and vulvar cancers. With speculum examination, the cervix may appear grossly normal if cancer is microinvasive. Visible disease displays varied appearances. Lesions may appear as exophytic or endophytic growth; as a polypoid mass, papillary tissue, or barrel-shaped cervix; as a cervical ulceration or granular mass; or as necrotic tissue (Fig. 30-9). A watery, purulent, or bloody discharge may also be present. For this reason, cervical cancer may mirror the appearance of different diseases. These include cervical leiomyoma, cervical polyp, prolapsing uterine sarcoma, vaginitis, cervical eversion, cervicitis, threatened abortion, placenta previa, cervical pregnancy, condyloma acuminata, herpetic ulcer, and chancre.

FIGURE 30-9



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of invasive cervical cancer originating from the endocervix. *(Courtesy of Dr. David Miller.)*

During bimanual examination, a clinician may palpate an enlarged uterus resulting from tumor invasion and growth. Alternatively, hematometra or pyometra may expand the endometrial cavity following obstruction of fluid egress by a primary cervical cancer. Advanced cervical cancer cases may have vaginal involvement, and the extent of disease can be appreciated on rectovaginal examination. In such cases, palpation of the rectovaginal septum between the index and middle finger of an examiner's hand reveals a thick, hard, irregular septum. The proximal posterior vaginal wall is most commonly invaded. In addition, during digital rectal examination, parametrial, uterosacral, and pelvic sidewall involvement can be palpated. Either one or both parametria may be invaded and involved tissues feel thick, irregular, firm, and less mobile. A fixed mass indicates that tumor has probably extended to the pelvic sidewalls. However, a central lesion can become as large as 8 to 10 cm in diameter before reaching these sidewalls.

Papanicolaou Smear

Histologic evaluation of cervical biopsy is the primary tool used to diagnose cervical cancer. Although Papanicolaou (Pap) smears are performed extensively to screen for this cancer, this test does not always detect cervical cancer. Specifically, Pap smear testing has only a 55- to 80-percent sensitivity for detecting high-grade lesions on any given single test (Benoit, 1984; Soost, 1991). Thus, the preventive power of Pap smear testing lies in regular serial screening as outlined in Table 29-3. Moreover, in women who have stage I cervical cancer, only 30 to 50 percent of single cytologic smears obtained are read as positive for cancer (Benoit, 1984). Hence, the use of Pap smear alone for evaluation of suspicious lesions is discouraged. Importantly, these lesions should be directly biopsied with Tischler biopsy forceps or a Kevorkian curette (see Fig. 29-11).

Colposcopy and Cervical Biopsy

If abnormal Pap smear findings are noted, colposcopy is performed as described in Chapter 29, Colposcopy. During this evaluation, the entire transformation zone ideally is identified, and adequate cervical and endocervical biopsies are obtained. Cervical punch biopsies or conization specimens are the most accurate for allowing assessment of cervical cancer invasion. Both sample types typically contain underlying stroma and enable differentiation between invasive and in situ carcinomas. Of these, conization specimens provide a pathologist with a larger tissue sample and are most helpful in diagnosing in situ cancers and microinvasive cervical cancers.

STAGING

Clinical Staging

Cervical cancers are staged clinically, and interpretations are preferably confirmed with a bimanual pelvic examination under anesthesia (Table 30-5). The staging system widely used for cervical cancer is that developed by FIGO in collaboration with the World Health Organization (WHO) and the International Union Against Cancer (UICC) (Table 30-6 and Fig. 30-10). In this chapter, *early stage disease* refers to FIGO stages I through IIA. The term *advanced stage disease* describes stages IIB and higher.

FIGURE 30-10

Drawing illustrates the FIGO stages of cervical cancer. *(From Quinn, 2006, with permission.)*

Table 30-5 Testing Used during Cervical Cancer Staging

Testing	**To Identify:**
Laboratory	
CBC	Anemia prior to surgery, chemotherapy, or radiotherapy
Urinalysis	Hematuria
Chemistry profile	
Liver function	Liver metastasis
Creatinine and BUN levels	Hydronephrosis
Radiologic	
Chest radiograph	Lung metastasis
Intravenous pyelogram (IVP)	Hydronephrosis
CT scan (abdomen and pelvis)	Lymph node metastasis, metastasis to other distant organs, and hydronephrosis
MR imaging	Local extracervical invasion + those for CT scan
PET scan	Lymph node metastasis
Procedural	
Cystoscopy	Tumor invasion into the bladder
Proctoscopy	Tumor invasion into the rectum
Examination under anesthesia	Extent of pelvic tumor spread

BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; MR = magnetic resonance; PET = positron emission tomography.

Table 30-6 Clinical Stages of Cervical Cancer (FIGO, Revised 1994)	
Stage	**Characteristics**
0	Carcinoma in situ, cervical intraepithelial lesion (CIN) 3
I	Carcinoma is strictly confined to cervix (extension to corpus should be disregarded)
IA	Invasion is limited to measured stromal invasion with a maximum depth of 5 mm and no wider than 7mm
IA1	Measured invasion of stroma no greater than 3 mm in depth and no wider than 7 mm
IA2	Measured invasion of stroma greater than 3 mm and no greater than 5 mm in depth and no wider than 7mm
IB	Clinical lesions confined to the cervix or preclinical lesions greater than IA
IB1	Clinical lesions no greater than 4 cm in size
IB2	Clinical lesions greater than 4 cm in size
II	Carcinoma extends beyond cervix but has not extended to pelvic wall; it involves vagina, but not as far as the lower third
IIA	No obvious parametrial involvement
IIB	Obvious parametrial involvement
III	Carcinoma has extended to the pelvic wall; on rectal examination there is no cancer-free space between tumor and pelvic wall; tumor involves lower third of vagina; all cases with hydronephrosis or nonfunctioning kidney should be included, unless they are known to be due to another cause
IIIA	No extension to pelvic wall, but involvement of lower third of vagina
IIIB	Extension to pelvic wall, or hydronephrosis or nonfunctioning kidney due to tumor
IV	Carcinoma has extended beyond true pelvis or has clinically involved mucosa of bladder or rectum
IVA	Spread of growth to adjacent pelvic organs
IVB	Spread to distant organs

FIGO = International Federation of Obstetricians and Gynecologists.

Modified from Quinn, 2006, with permission.

COMPUTED TOMOGRAPHY SCANNING

This is frequently used as a sole imaging study for identifying hydronephrosis, determining the extent of metastasis, and treatment planning. Specifically, computed tomography (CT) scanning has been most valuable in evaluation of para-aortic lymph nodes. For these nodes, CT scanning has a specificity of 100 percent and a sensitivity of 67 percent. However, for pelvic nodes, its sensitivity of 25 percent is substantially lower (Camilien, 1988). Alternatively, lymphangiography may be performed and has 79-percent sensitivity and 73-percent specificity. Its use, however, for cervical cancer staging is uncommon (Heller, 1990).

MAGNETIC RESONANCE IMAGING

This radiologic tool may also aid clinical staging, primarily by determining extracervical extension. In this role, magnetic resonance (MR) imaging is accurate in localizing cervical tumors, excluding parametrial invasion, and confirming myometrial and internal cervical os invasion (Sahdev, 2007). Moreover, for para-aortic nodal metastasis, MR imaging offers sensitivity comparable with CT scanning.

POSITRON EMISSION TOMOGRAPHY

This nuclear medicine study uses radioisotope tagged substrates such as glucose (2-[18F]-fluoro-2-deoxy-D glucose [FDG]) and creates images based on substrate metabolism within the body. In detecting para-aortic nodal metastasis in women with cervical cancer, preliminary experience has shown a cumulative sensitivity of 78 percent (Lin, 2003; Narayan, 2001; Rose, 1999a; Yeh, 2002). Moreover, positron emission tomography (PET) scanning may allow improved prediction of clinical outcome compared with CT scanning. For example, Grigsby and colleagues showed that the survival rate after pelvic radiation therapy for patients with FDG para-aortic nodal uptake (PET+) and with normal para-aortic anatomy identified by CT scanning was identical to that of patients with PET+ and abnormal para-aortic nodes by CT scanning (Grigsby, 2001).

Surgical Staging

LYMPH NODE DISSECTION

Surgical evaluation of retroperitoneal lymph nodes offers accurate detection of pelvic and para-aortic metastasis. In addition, debulking of tumor-laden nodes is also achieved. As a result, lymph node dissection may enhance management of and improve survival rates in patients with advanced stage cervical cancer.

During this dissection, most experts recommend lymph node biopsy in the common iliac and para-aortic region and selective biopsy of macroscopic lymph nodes (Querleu, 2000). Traditional laparotomic transperitoneal and extraperitoneal as well as laparoscopic approaches to these procedures have been studied. Although diagnostically equivalent, laparoscopic approaches offer the postoperative advantages of laparoscopic surgery. In addition, laparoscopic node dissection has been associated with significantly less radiation morbidity than radiation following laparotomic approaches (Vasilev, 1995).

One advantage to surgical staging is its improved sensitivity to detect pelvic and para-aortic nodal metastasis more accurately than radiologic techniques (Goff, 1999). Surgical staging enables the detection of microscopic metastasis and confirms macroscopic nodal metastasis. Moreover, for those with locally advanced cervical cancer, surgical staging can be performed with acceptable morbidity, and findings may modify a patient's primary treatment strategy based on the level of nodal metastasis. Retrospective studies have suggested a statistically significant survival benefit to extended chemotherapy and/or extended field radiation therapy if positive pelvic/para-aortic nodes are identified (Hacker, 1995; Holcomb, 1999).

In addition to its diagnostic power, surgical staging also permits debulking of grossly positive nodes. As a result, radiation fields during radiotherapy may be modified and lead to fewer radiotherapy complications.

However, evidence supporting a survival benefit from de-bulking macroscopic para-aortic nodes is contradictory. Although some retrospective studies have shown that disease-free survival rates for patients whose macroscopic nodal disease has been resected is similar to that of women with microscopic nodal disease, this benefit does not extend to overall survival rates (Cosin, 1998; Hacker, 1995).

Despite these suggested benefits, some experts argue that the benefits of surgical staging, if any, are minimal. These studies estimate only a 4- to 6-percent survival benefit after aggressive surgical debulking of retroperitoneal lymph nodes (Kupets, 2002; Petereit, 1998).

Prognosis

PROGNOSTIC FACTORS

The significance of tumor burden on survival has been well demonstrated, whether measured by FIGO stage, centimeter size, or surgical staging (Stehman, 1991). Of these definers, FIGO stage is the most significant prognostic factor (Fig. 30-11 and Table 30-

7). However, within each stage distribution, lymph node involvement also becomes an important factor in determining prognosis. For example, in early stage cervical cancer (stages I through IIA), nodal metastases are an independent predictor of survival (Delgado, 1990; Tinga, 1990). A GOG study demonstrated an 86-percent, 3-year survival for women with early stage cervical cancer and negative pelvic lymph nodes, compared with a 74-percent similar survival in patients who had one or more positive lymph nodes (Delgado, 1990).

In addition, the number of nodal metastases is also predictive. Retrospective studies have demonstrated significantly higher 5-year survival rates in those with one positive lymph node compared with women with multiple involved nodes (Tinga, 1990). Similarly, the negative prognostic impact of lymph node involvement in advanced stage (stage IIB through IV) cervical cancer has been demonstrated by several authors. In general, microscopic nodal involvement has a better prognosis than macroscopic nodal disease (Cosin, 1998; Hacker, 1995).

TREATMENT

Primary Disease

STAGE IA

The term *microinvasive cervical cancer* identifies this subgroup of small tumors. Specifically, as seen in Table 30-6, criteria for stage IA tumors limits invasion depth to no greater than 5 mm and lateral spread to no wider than 7 mm (Fig. 30-12). Microinvasive cervical cancer carries a minor risk of lymph node involvement and excellent prognosis following treatment. A retrospective study compared tumors with horizontal spread less than or equal to 7 mm and those with greater than 7 mm spread. Higher rates of pelvic lymph node metastasis and recurrence rates were noted as tumor spread further than 7 mm (Takeshima, 1999).

Photomicrograph of microinvasive squamous cell cervical cancer. Microinvasive squamous cell carcinomas are not grossly visible and are identified microscopically. These foci are not to exceed 5 mm in depth or 7 mm in lateral spread. *(Courtesy of Dr. Raheela Ashfaq.)*

Stage IA tumors are further divided into IA1 and IA2. These cancers are subdivided to reflect increasing depth and width of invasion and increasing risks for lymph node involvement (see Table 30-6).

Stage IA1

These tumors invade no deeper than 3 mm, spread no wider than 7 mm, and are associated with the lowest risk for lymph node involvement. Squamous cervical cancers with stromal invasion less than 1 mm have a 1-percent risk of nodal metastasis, and those with 1 to 3 mm of stromal invasion carry a 1.5-percent risk. Of 4,098 women studied with this tumor stage, less than 1 percent died of disease (Ostor, 1995). Such evidence supports conservative management of stage IA1 squamous cell cancer if lymphovascular space invasion (LVSI) is absent. These lesions may be effectively treated with cervical conization alone (Keighley, 1968; Kolstad, 1989; Morris, 1993; Ostor, 1994). However, a total intrafascial hysterectomy (type I hysterectomy) via an abdominal, vaginal, or laparoscopic approach is preferred for women who have completed childbearing.

The presence of LVSI in stage IA1 microinvasive cancers increases the risk of lymph node metastasis and cancer recurrence to approximately 5 percent. Accordingly, at our institution, these cases are traditionally managed with modified radical hysterectomy (type II hysterectomy) and pelvic lymphadenectomy.

Adenocarcinomas are typically diagnosed at a more advanced stage than squamous cell cervical cancers. Thus, microinvasive adenocarcinomas present a unique management dilemma, due to sparse data regarding this tumor stage. However, based on evaluation of Surveillance Epidemiology and End Result (SEER) data provided by the National Cancer Institute, the incidence of lymph node involvement is similar to that of squamous cancers (Smith, 2002). Of microinvasive cervical adenocarcinomas, 21 cases managed with uterine preservation and conization have been reported in the literature (Andersen, 2002; Schorge, 2000). Of these cases, no recurrences were identified following brief surveillance.

Stage IA2

Cervical lesions with 3 to 5 mm of stromal invasion have a 7-percent risk of lymph node metastasis and a greater than 4-percent risk of disease recurrence. In this group of women, the safety of conservative therapy is yet to be proven. Thus, for this degree of microinvasion modified radical hysterectomy and pelvic lymphadenectomy is warranted.

A few authors have reported management of stage IA2 squamous cervical lesions with radical trachelectomy and lymphadenectomy for fertility preservation. Several studies have also recommended that a nonabsorbable cerclage be placed concurrently with such radical trachelectomy to improve cervical competence during pregnancy. These procedures have high cure rates and successful pregnancies have been reported. If women are carefully selected for younger age, lower body mass index (BMI), smaller tumor size (<2 cm), and negative nodal involvement, then reported recurrence rates are similar to those of radical hysterectomy (Burnett, 2003; Covens, 1999a, 1999b). Preoperative MR imaging is recommended in these cases. If tumor has extended past the internal cervical os, then trachelectomy is contraindicated. Although this technique is promising, it carries a learning curve, and further studies to validate its efficacy are needed.

Alternatively, patients with microinvasive carcinoma (stages IA1 and IA2) can be treated with intracavitary brachytherapy alone with excellent results (Grigsby, 1991; Hamberger, 1978). Potential candidates for vaginal brachytherapy include women who are elderly, are not surgical candidates due to other concurrent medical disease, or do not wish to preserve ovarian or sexual function.

RADICAL HYSTERECTOMY

Women with FIGO stage IA2 through IIA cervical cancer may be selected for radical hysterectomy. In addition, surgery is appropriate for those who are physically able to tolerate an aggressive surgical procedure, those who wish to avoid the long-term effects of radiation therapy, and/or those who have contraindications to pelvic radiotherapy. Typical candidates include young patients who desire ovarian preservation and retention of a functional, nonirradiated vagina.

Simple Hysterectomy (Type I)

Hysterectomy techniques vary depending on the degree of surrounding support that is resected and are categorized as type I, II, or III. Type I hysterectomy, also known as an *extrafascial hysterectomy* or *simple hysterectomy* , removes the uterus and cervix, but does require excision of the parametrium or paracolpium. It is appropriately selected for benign gynecologic pathology, preinvasive cervical disease, and stage IA1 cervical cancer.

Modified Radical Hysterectomy (Type II)

Modified radical hysterectomy removes the cervix, proximal vagina, and parametrial and paracervical tissue (see Section 43-2, Modified Radical Abdominal Hysterectomy (Type II)). The ureters are unroofed from the paracervical tunnel until their point of entry into the bladder. They are then retracted laterally to enable removal of the parametrial and paracervical tissue medial to the ureter. This hysterectomy is well suited for tumors with 3- to 5-mm depths of invasion and smaller stage IB tumors (Landoni, 2001).

Radical Hysterectomy (Type III)

This hysterectomy requires greater resection of the parametria, and excision extends to the pelvic sidewall (Fig. 30-13) (see Section 43-1, Radical Abdominal Hysterectomy (Type III)). The ureters are completely dissected from their beds, and the bladder and rectum are mobilized to permit this more extensive removal of tissue. In addition, at least 2 to 3 cm of proximal vagina is

resected. This procedure is performed for larger IB lesions, and for patients with relative contraindications to radiation such as diabetes, pelvic inflammatory disease, hypertension, collagen disease, or adnexal masses.

FIGURE 30-13

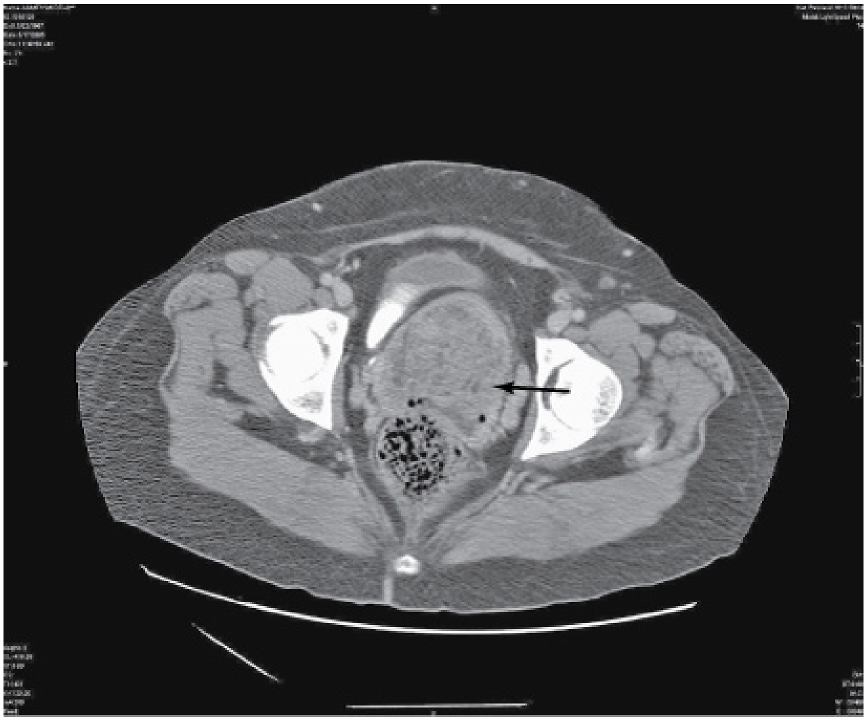
Gross surgical specimen following radical hysterectomy. The specimen includes the uterus, adnexa, and parametria **(arrows)** .

STAGE IB TO IIA

Stage IB lesions are defined as those extending past the limits of microinvasion yet still confined to the cervix. This stage is subcategorized either as IB1 if tumors measure ≤4 cm or as IB2 if they measure >4 cm (Fig. 30-14).

FIGURE 30-14



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

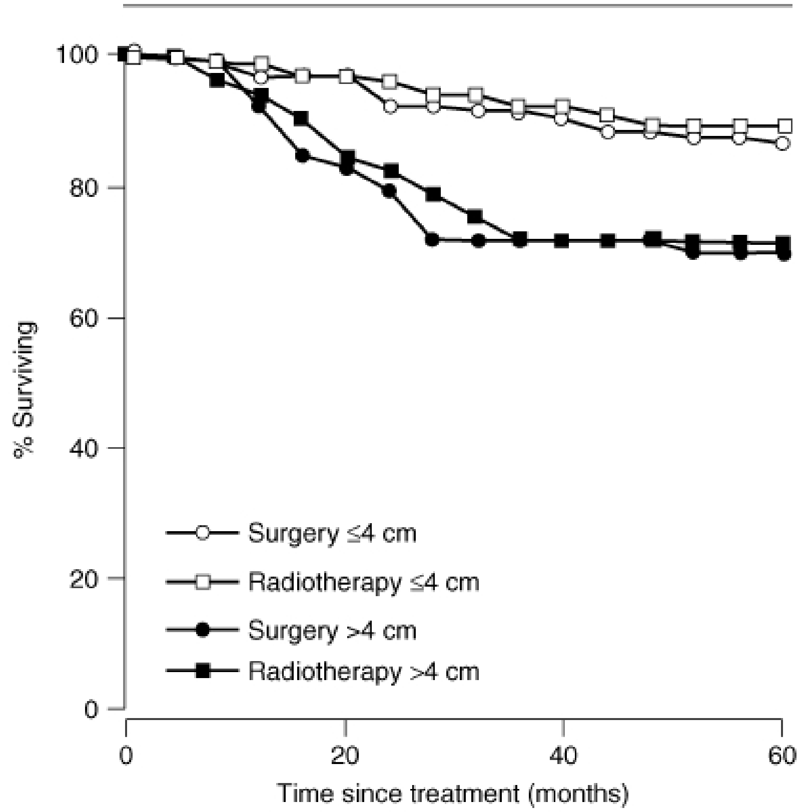
Computed tomography (CT) scan of stage IB2 cervical cancer. *(Courtesy of Dr. John Schorge.)*

Stage II cancers extend outside the cervix. They may invade the upper vagina and the parametria but do not reach the pelvic sidewalls. Stage IIA tumors have no parametrial involvement, but do extend vaginally as far as the proximal two thirds of the vagina. Stage IIB cancer may invade the vagina to a similar extent as well as invade the parametria.

Treatment of Stage IB to IIA Tumors

These cancers can be managed either with surgery or radiation therapy (Fig. 30-15). In a prospective study of primary therapy, 393 women were randomly assigned to undergo radical hysterectomy and pelvic lymphadenectomy or receive primary radiation therapy. Five-year overall survival and disease-free survival were statistically equivalent (83 percent and 74 percent, respectively). Surgical patients, however, had significantly greater severe morbidity rates compared with the radiotherapy group (Landoni, 1997).

FIGURE 30-15



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Graph shows equivalent overall survival rates whether stage IB through IIA tumors are treated surgically or with radiation therapy. *(From Landoni, 1997, with permission.)*

Because radiotherapy and surgery are both viable options, the optimum treatment for each woman ideally should assess clinical factors such as menopausal status, age, concurrent medical illness, tumor histology, and cervical diameter. For stage IB1 cervical cancers, it is left to the physician's discretion and patient preference as to which treatment modality is preferred. Our general approach to patients with stage IB2 and stage II cervical cancers is to manage them primarily with chemoradiation, in a similar fashion to advanced stage cervical cancers.

In general, radical hysterectomy for stage IB through IIA tumors is usually selected for young women with low BMIs who wish to preserve ovarian function and have concerns about altered sexual functioning following radiotherapy (see Chap. 28, Ovary and Pregnancy Outcomes). Age and weight are not contraindications to surgery, although in general, older women may have longer hospital stays and heavier women can have longer operative time, greater blood loss, and higher rates of wound complications. Surgery is contraindicated in patients with severe cardiac or pulmonary disease or prior thromboembolism.

In those electing surgery, oophorectomy may be deferred in younger women. One GOG study evaluated tumor spread to the ovary in those with IB tumors electing radical hysterectomy without adnexectomy. Ovarian metastases were identified in only 0.5 percent of 770 women with stage IB squamous cell cancers and in 2 percent of those with adenocarcinomas (Sutton, 1992).

Surgical and Radiotherapy Complications

Complications for early-stage cervical cancer surgery include ureteral stricture, bladder dysfunction, constipation, wound breakdown, lymphocyst, and lymphedema. In addition, radiotherapy added as an adjuvant to surgery increases the risk of these

complications.

On the other hand, radiation therapy also may be associated with long-term complications. Altered sexual function secondary to a shortened vagina, dyspareunia, psychological factors, and vaginal stenosis are often encountered. Late urinary and bowel complications such as fistula formation, enteritis, proctitis, and bowel obstruction may also develop following radiotherapy.

POSITIVE PELVIC LYMPH NODES

Approximately 15 percent of patients with stage I through IIA cervical cancers will have positive pelvic nodes. Risk factors for lymph node involvement include those listed in Table 30-8. Of those with involved nodes, 50 percent will have grossly positive pelvic nodes intraoperatively. In most cases, radical hysterectomy is abandoned, and whole-pelvic radiation with subsequent brachytherapy is administered.

Table 30-8 Frequency of Positive Pelvic Lymph Nodes by Pathologic Factors for Patients with Squamous Cell Carcinoma, No Gross Disease beyond the Uterus and Cervix, and Negative Aortic Nodes

Factor	**Frequency with Positive Pelvic Lymph Nodes (%)**		***p***

RECURRENCE RISK

Intermediate Risk of Recurrence

The GOG has defined recurrence risk factors that would identify women who undergo radical surgery for early-stage cervical cancer. *Intermediate risk* describes those who on average would have a 30-percent risk of cancer recurrence within 3 years. Factors included in this model are depth of tumor invasion, tumor diameter, and LVSI.

To determine appropriate treatment of these at-risk women, patients with these intermediate-risk factors have been studied. In one study, women were randomly assigned to receive pelvic radiation therapy following radical hysterectomy or radical hysterectomy and observation. A nearly 50-percent reduced risk of recurrence was found in those who received postoperative adjuvant radiation therapy (Sedlis, 1999). However, this adjuvant radiation does not prolong overall survival. In our practice, these intermediate-risk patients are counseled regarding their risk of recurrence and offered the option of adjuvant radiation therapy.

High Risk of Recurrence

A high-risk category of patients who undergo radical surgery for early-stage cervical cancer has also been described. *High-risk* is defined as a 50- to 70-percent risk of recurrence within 5 years. These women have positive lymph nodes, positive surgical margins, or microscopically positive parametria (Peters, 2000).

This group is routinely offered adjuvant radiation therapy. Moreover, the GOG recently demonstrated that the addition of concurrent chemotherapy consisting of cisplatin and 5-FU would be beneficial in significantly prolonging disease-free and overall survival in this group of women with high-risk early stage cancer (Peters, 2000).

Adjuvant Hysterectomy Following Primary Radiation

Benefits of treating bulky stage I (IB2) cervical cancers with adjuvant hysterectomy following radiation therapy has been evaluated. Adjuvant hysterectomy reduces locoregional relapse, but does not contribute to an overall improvement in survival. However, initial lesion size may affect efficacy. In one study, those with tumors measuring less than 7 cm who underwent postradiation hysterectomy survived longer compared with women with equivalent tumors in the radiation-only regimen group. In contrast, those with lesions 7 cm or larger who underwent postradiation hysterectomy fared worse than their counterparts receiving only radiotherapy (Keys, 2003).

EARLY STAGE CERVICAL ADENOCARCINOMA

These cancers may be more radioresistant than squamous cell cervical carcinomas. Although some prefer radical hysterectomy to radiotherapy, studies suggest equivalent survival rates with both (Eifel, 1990, 1991, 1995; Hopkins, 1988; Nakano, 1995). However, larger lesions may not regress if managed by radiation alone (Leveque, 1998; Silver, 1998). In bulky tumors, their centers may be less radiosensitive due to relative cellular hypoxia (see Chap. 28, Radiation Biology). This effect underscores the advantages of radical hysterectomy for women with stage I cervical adenocarcinoma.

STAGES IIB THROUGH IVA

Advanced-stage cervical cancers extend past the confines of the cervix and often involve adjacent organs and retroperitoneal lymph nodes. As such, treatment for these tumors must be individualized to maximize patient outcome. The vast majority of advanced-stage tumors have poor prognosis, and 5-year survival rates are less than 50 percent. Advanced-stage tumors represent a large proportion of invasive cervical cancers treated, depending on the geographic area studied. If untreated, these tumors progress rapidly.

Radiation Therapy

This modality forms the cornerstone of advanced-stage cervical cancer management. Both external beam pelvic radiation and brachytherapy are typically delivered (see Chap. 28, Radiation Therapy). Of these, external beam radiation usually precedes intracavitary radiation, which is one form of brachytherapy. External beam radiation is commonly administered in 25 fractions during 5 weeks. During brachytherapy, to limit bladder and rectal doses, bowel and bladder are packed away from the intracavitary source during tandem insertion, using vaginal packing. During staging, if para-aortic nodal metastases are found, then extended field radiation can be added to treat these affected lymph nodes.

Chemoradiation

Current evidence indicates that concurrent chemotherapy significantly improves overall and disease-free survival of women with advanced cervical cancer. Thus, most patients with stage IIB through IVA cervical cancer are best treated with chemoradiation. Cisplatin-containing regimens have been associated with the best survival rates (Rose, 1999b; Whitney, 1999). Chemoradiation is also associated with superior survival rates compared with pelvic and extended field para-aortic region irradiation alone (Morris, 1999). At our institution, cisplatin is given weekly for 5 weeks and is administered concurrently with radiotherapy.

Pelvic Exenteration for Primary Disease

This surgery encompasses removal of the bladder, rectum, uterus (if present), and surrounding tissues (see Section 43-3, Total Pelvic Exenteration). Primary exenteration may be considered for women with stage IVA cancer, that is, with direct tumor invasion into bladder and/or bowel without distant spread. For this indication, however, it is rarely performed. Yet for women with stage IVA cervical cancer and extension solely into the bladder, the survival rate can reach 30 percent (Million, 1972; Upadhyay, 1988).

STAGE IVB

Patients with stage IVB disease have a poor prognosis and are treated with a goal of palliation. Pelvic radiation is administered to control vaginal bleeding and pain. Systemic chemotherapy is offered to palliate symptoms. The chemotherapy regimens used in this group of women is similar to those used in the setting of recurrent cancer.

Surveillance

FOLLOWING RADIOTHERAPY

Women who receive radiotherapy should be closely monitored to assess their response. Tumors may be expected to regress for up to 3 months after therapy. Pelvic examination and/or radiologic scanning should document progressive shrinkage of the cervical mass. The rectovaginal examination should be used to detect nodularity in the ligaments and parametria. If disease progresses locally after this interval, surgery should be considered. Typically, pelvic exenteration is indicated for this clinical setting.

In addition to pelvic examination, a thorough manual nodal survey should include neck, supraclavicular, infraclavicular, axillary, and inguinal lymph nodes. In addition, a chest radiograph can be obtained yearly. Cervical or vaginal cuff Pap smear should also be collected every 3 months for 2 years and then every 6 months for 3 years. Findings of low-grade or high-grade squamous intraepithelial lesion should prompt colposcopic evaluation. If high-grade lesion or cancer is noted on cervical biopsy, then CT

scanning to assess disease recurrence is indicated.

FOLLOWING SURGERY

After a radical hysterectomy, 80 percent of recurrences are detected within the subsequent 2 years. During patient surveillance, identification of an abnormal pelvic mass or abnormal pelvic examination, pain radiating down the posterior thigh, or new-onset lower extremity edema should prompt CT scanning of the abdomen and pelvis. Pelvic recurrences after radical hysterectomy, if diagnosed early, can be salvaged with radiation therapy.

Secondary Disease

Secondary disease is defined as either persistent or recurrent cancer. Cervical cancer that has not completely regressed within 3 months of radiotherapy is considered persistent. Disease recurrence is defined as a new lesion after completion of primary therapy.

Treatment of persistent or recurrent disease depends on its location and extent. The intent in these cases is usually palliative. However, in certain instances, a woman may qualify for pelvic radiation if she previously had not received this treatment. Alternatively, a woman may be a candidate for a curative-intent surgical procedure. All chemotherapy-based treatments of metastatic disease are administered with a goal of palliation. In these cases, the primary focus is to maximize existing patient quality of life.

PELVIC EXENTERATION FOR SECONDARY DISEASE

When curative-intent surgery is contemplated, local disease should be biopsy proven. Clinically, a patient may be considered for pelvic exenteration if lower extremity edema, back pain, and hydronephrosis are absent. If present, these suggest disease extension to the pelvic side walls, which would contraindicate surgery. In addition, regional and distant metastasis should be excluded by both physical examination and radiologic imaging.

Pelvic exenteration begins with exploratory laparotomy, biopsies of suspicious lesions, and pelvic and para-aortic lymph node evaluation. Exenteration is completed only if there is no disease in frozen section specimens sampled during surgery. A complete surgical description of this procedure is found in Section 43-3, Total Pelvic Exenteration.

Alternatively, in highly selected patients radical hysterectomy may be considered an alternative to pelvic exenteration (Coleman, 1994). In these circumstances, women should have small cervical recurrences measuring less than 2 cm and have disease-free pelvic lymph nodes both prior to and during surgery. With either surgical procedure, intraoperative and postoperative complications can be significant.

RADIOTHERAPY FOR SECONDARY DISEASE

Patients with central or limited peripheral recurrences who are radiotherapy naive are candidates for curative-intent radiation treatment. In these groups, survival rates of 30 to 70 percent have been reported (Ijaz, 1998; Ito, 1997; Lanciano, 1996; Potter, 1990).

CHEMOTHERAPY FOR SECONDARY DISEASE

Antineoplastic drugs are used to palliate both disease and symptoms of advanced, persistent, or recurrent cervical cancer (Table 30-9). Cisplatin is considered the single most active cytotoxic agent in this setting (Thigpen, 1995). Overall, response duration to cisplatin is 4 to 6 months, and survival in such women only approximates 7 months (Vermorken, 1993). Recently, a prospective randomized study demonstrated that the combination of cisplatin with topotecan confers a survival advantage to this group of patients, compared with cisplatin alone (GOG protocol #179). Moreover, ongoing GOG studies aim to determine the best combination cytotoxic chemotherapy for women with recurrent or persistent cervical cancer.

Table 30-9 Combination Chemotherapy Regimens and Response Rates of Cervical Cancer				
Study	**Chemotherapy Agents**	**Response Rates**	**Progression-free Survival**	**Overall Survival**
Moore, 2004	Cisplatin vs. cisplatin and taxol (Phase III)	19% vs. 36%	2.8 vs. 4.8 months	No difference
Long, 2005	Cisplatin vs. cisplatin and topotecan (Phase III)	13% vs. 27%	2.9 vs. 4.6 months	6.5 vs. 9.4 months
Morris, 2004	Cisplatin and vinorelbine (Phase II)	30%	5.5 months	
Brewer, 2006	Cisplatin and gemcitabine (Phase II)	22%	2.1 months	

Palliative Care

Palliative chemotherapy is administered only if this treatment does not cause significant decline in patient quality of life. Any decision for treatment of cervical cancer in a palliative care setting should be assessed against the benefits of supportive care. Women with persistent nausea and vomiting from tumor-associated ileus may benefit from a gastrostomy tube. Urinary fistulas and bowel obstruction can be managed surgically, provided a patient is an appropriate surgical candidate. Pain management forms the basis of palliation and an extensive list of pain medications is found in Table 39-15.

We recommend discussion of medical directives if a patient has adequate mental capability. Often, such discussion is conducted over time, giving a woman an opportunity to understand the nature and progression of her disease. Home hospice is an invaluable part of terminal care for most of these women, who require intense pain management and considerable assistance with daily living activities.

Management during Pregnancy

There is no difference in survival between pregnant and nonpregnant women with cervical cancer when matched by age, stage, and year of diagnosis. As with nonpregnant women, clinical stage at diagnosis is the single most important prognostic factor for cervical cancer during pregnancy. Overall survival is slightly better for cervical cancer in pregnancy because an increased proportion of patients have stage I disease.

DIAGNOSIS

A Pap smear is recommended for all pregnant patients at the initial prenatal visit. Additionally, clinically suspicious lesions should be directly biopsied. If Pap test results reveal HSIL or suspected malignancy, then colposcopy is performed and biopsies are obtained. However, endocervical curettage is excluded. If Pap testing indicates malignant cells and colposcopic-directed biopsy fails to confirm malignancy, then diagnostic conization may be necessary. Conization is recommended only during the second trimester and only in patients with inadequate colposcopic findings and strong cytologic evidence of invasive cancer. Conization is deferred in the first trimester, as this surgery is associated with abortion rates of 30 percent in this part of pregnancy.

STAGE I CANCER IN PREGNANCY

Women with microinvasive squamous cell cervical carcinoma measuring 3 mm or less and containing no LVSI may deliver vaginally and be re-evaluated 6 weeks postpartum. Moreover, for those with stage IA or IB disease, studies find no increased maternal risk if treatment is intentionally delayed to optimize fetal maturity regardless of the trimester in which the cancer was diagnosed. Given the outcomes, a planned treatment delay is generally acceptable for women who are 20 or more weeks' gestational age at diagnosis with stage I disease and who desire to continue their pregnancy. However, a patient may be able to delay from earlier gestational ages if she wishes.

ADVANCED CERVICAL CANCER IN PREGNANCY

Women with advanced cervical cancer diagnosed prior to fetal viability are offered primary chemoradiation. Spontaneous abortion

of the fetus tends to follow whole-pelvis radiation therapy. If cancer is diagnosed after fetal viability is reached and a delay until fetal pulmonary maturity is elected, then a classical cesarean delivery is performed. A classical cesarean incision minimizes the risk of cutting through tumor in the lower uterine segment, which can cause serious blood loss. Chemoradiation is administered after uterine involution. For patients with advanced disease and treatment delay, pregnancy may impair prognosis. Women who elect to delay treatment, to provide quantifiable benefit to their fetus, will have to accept an undefined risk of disease progression.

INVASIVE CANCER OF THE VULVA: INTRODUCTION

Vulvar cancer is primarily a disease of elderly women but has been observed in premenopausal women as well. These cancers are uncommon and comprise approximately 5 percent of all gynecologic malignancies. As a result, a general clinician's experience with these lesions may be limited.

Vulvar tumors typically produce symptoms of pruritus and irritation. Minor symptoms may be initially ignored by women, contributing to a delay in diagnosis. Additionally, diagnostic delays may follow topical therapy by providers for presumed other dermatoses prior to establishing a pathologic diagnosis. Thus, early detection and biopsy of any abnormal vulvar lesion are imperative to diagnosing vulvar cancer in its early stages.

Almost 90 percent of vulvar tumors are squamous cell carcinomas. Accordingly, virtually all knowledge regarding prognostic factors, spread patterns, and survival information is based on review of women with this tumor type. Although rare, uncommon histologic subtypes such as melanomas, basal cell carcinomas, Bartholin gland adenocarcinomas, and various other soft tissue sarcomas also may be encountered (Table 31-1).

Table 31-1 Incidence of Vulvar Neoplasms by Histologic Type[a]

Tumor Type	Percent	
Epidermoid	86.2	
Melanoma	4.8	
Sarcoma	2.2	
Basal cell	1.4	
Bartholin gland		
Squamous	0.4	1.2
Adenocarcinoma	0.6	
Adenocarcinoma	0.6	
Undifferentiated	3.9	

[a] Based on 1,378 reported cases.

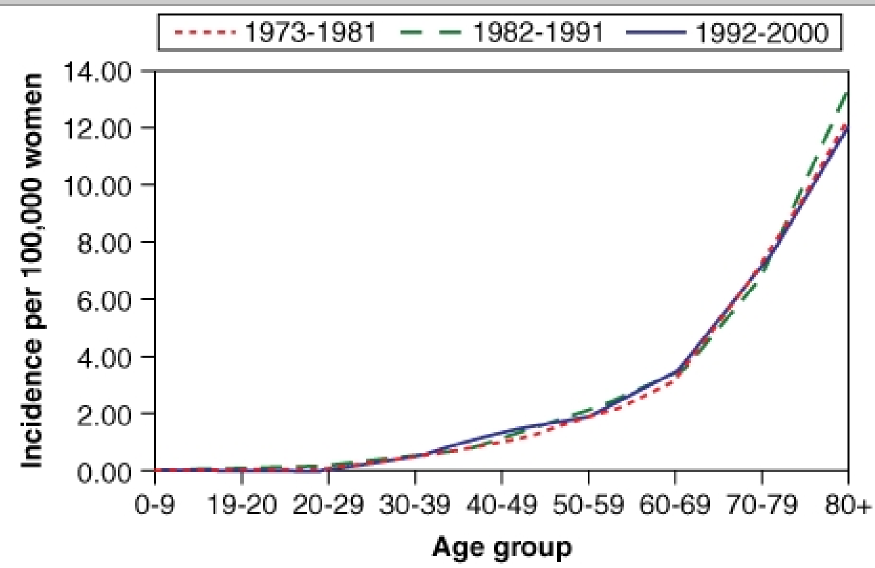
Modified from Plentl, 1971, with permission.

Most vulvar squamous cell cancers, when found early, carry a good prognosis. Traditional therapy includes radical excision of the vulva and inguinal lymph nodes. Adjuvant radiation therapy is instituted occasionally. Despite its infrequency, vulvar cancer remains an important female disease because of its significant impact on sexuality. Over the past decade, numerous advances have been made in the management of vulvar cancer, with a trend toward more conservative surgery and improved psychosexual outcomes.

INCIDENCE

Vulvar cancer's incidence increases steadily with age and peaks in the seventh decade of life (Cavanagh, 1986; Green, 2000; Morgan, 1999; Taussig, 1949; Thomas, 1991; Trope, 1991; Way, 1960) (Fig. 31-1). For this reason, the steady increase in life expectancy has brought carcinoma of the vulva increased attention among gynecologic malignancies.

FIGURE 31-1



The incidence of invasive vulvar cancer increase with age. *(From Judson, 2002, with permission.)*

According to the National Center for Health Statistics and the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute 2006 data, there were an estimated 3,740 new cases of vulvar cancer and 880 deaths (Jemal, 2006). Vulvar cancer has an age-adjusted death rate of 0.2 per 100,000 women according to the 2000 U.S. standard population.

PATHOPHYSIOLOGY

Most vulvar malignancies arise within squamous epithelium. Although the vulva does not have an identifiable transformation zone, squamous neoplasias arise most commonly at the border of vulvar keratinized stratified squamous epithelium and the nonkeratinized squamous mucosa of the vestibule. In addition, most vulvar cancers arise within recognized areas of epithelial cell abnormality. For example, approximately 60 percent of cases have adjacent vulvar intraepithelial neoplasia (VIN), and 15 to 40 percent of cases are associated with lichen sclerosus.

Human Papillomavirus Infection

Based on etiologic and histopathologic characteristics, vulvar squamous cell carcinoma is suspected to develop via two separate pathways. One pathway leads mainly to nonkeratinizing (basaloid and/or warty) carcinomas and primarily affects younger women. In this pathway, infection with high-risk human papillomavirus (HR-HPV) is found. Serotypes 16 and 18 predominate, although HPV serotypes 18, 31, 33, and 45 also have been reported (see Chap. 29, Incidence) (van der Avoort, 2006). This type of carcinoma in general carries a significantly better prognosis than HPV-negative cancer.

The second pathway is rarely associated with HR-HPV, occurs in older women, leads to mostly differentiated keratinizing squamous cell carcinoma, and develops in a background of nonneoplastic epithelial disorders, such as lichen sclerosus.

Patterns of Spread

Vulvar cancers spread via the classic mechanisms of malignancy, which include local growth and extension into adjacent organs, embolization into regional lymph nodes, and hematogenous dissemination to distant sites.

HEMATOGENOUS SPREAD

Blood supply to the vulva is derived primarily from the internal pudendal vessels, which stem from an anterior branch of the internal iliac vessels (see Fig. 38-22). The internal pudendal vessels exit the pelvis and travel around the ischial spine to reach the posterolateral vulva and divide into several smaller branches to supply the vulva (see Fig. 38-28).

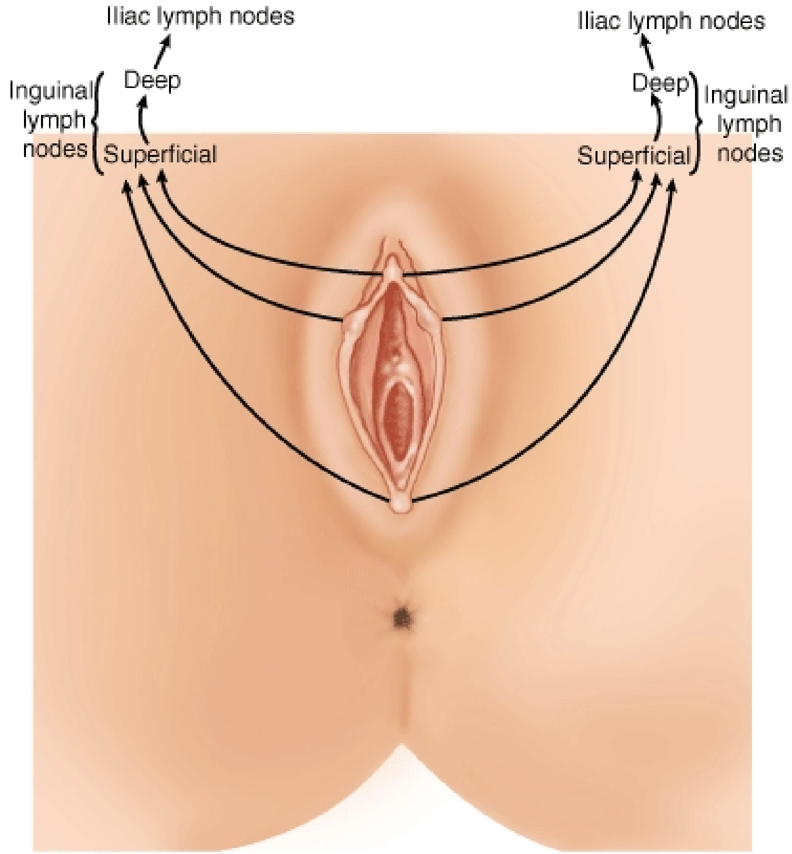
The deep external pudendal artery and the superficial pudendal artery are branches of the femoral artery that drain into the great saphenous vein (see Fig. 38-29). Both arteries supply the labia majora and their deep structures. They share anastomotic connections with branches of the internal pudendal vessels in areas where their tributaries mutually contribute blood supply.

LYMPHATIC SPREAD

Lymphatic vessels of the vulva drain primarily into the superficial inguinal lymph nodes. These nodes are located within a triangle formed by the inguinal ligament, the medial border of the sartorius muscle, and the lateral border of the adductor longus muscle (see Fig. 38-29). The phrase *pelvic lymph nodes* collectively defines the iliac and obturator lymph nodes, whereas the term *inguinofemoral lymph nodes* is often used to describe the collective deep and superficial inguinal nodes.

In general, lymphatic drainage travels in a stepwise fashion from the superficial to the deep inguinal nodes and then to pelvic lymph nodes (Fig. 31-2). Any spread beyond the inguinal nodes is considered distant metastasis.

FIGURE 31-2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Typical lymphatic drainage pattern with vulvar cancer. *(From Stenchever, 2001, with permission.)*

Vulvar lymphatics decussate in the mons pubis and the posterior fourchette. Lymphatics do not cross the labiocrural folds and generally do not cross the midline unless originating at the clitoris or at the perineal body (Morley, 1976). As a result, metastasis to contralateral nodes is rare in the absence of ipsilateral groin metastasis. *Ipsilateral* tumors can be defined as lesions that are further than 1 cm from the midline.

Infrequently, aberrant channels course directly from the tumor to ipsilateral deep inguinal or pelvic lymph nodes or to contralateral lymph nodes. These anatomic variants ultimately may explain unanticipated cancer recurrence following lymph node dissection in which no nodal metastasis was found.

With vulvar cancer, in-transit metastases are rare and suggest that initial lymphatic spread within the vulvar skin is exceedingly uncommon. In general, *in-transit metastases* are those that develop within regional dermal and subdermal lymphatics before reaching superficial inguinal nodes. These metastases lie more than 2 cm from the primary lesion but within the inguinal nodal drainage basin. In-transit metastases are differentiated from *satellite lesions,* which are skin or subcutaneous lesions within 2 cm of the primary tumor. These are considered intralymphatic extensions of the primary mass.

EPIDEMIOLOGY AND RISK FACTORS

As described earlier, two models for development of vulva cancer have been suggested, and risk factors for these two types vary (Table 31-2).

Table 31-2 Models of Vulvar Cancer

Characteristic	Type 1	Type 2
Age	Younger (35â€“65 years)	Older (55â€“85 years)
Cervical neoplasia	High association	Low association
Cofactors	Age, immune status, viral integration	Vulvar atypia, possibly mutated host genes
Histopathology of tumor	Intraepithelial-like (basaloid), poorly differentiated	Keratinizing; squamous cell carcinoma, well differentiated
HPV DNA	Frequent (>60%)	Seldom (<15%)
Pre-existing lesion	VIN	Vulvar inflammation, lichen sclerosus, squamous cell hyperplasia
History of condyloma	Strong association	Rare association
History of STD	Strong association	Rare association
Cigarette smoking	High incidence	Low incidence

HPV = human papillomavirus; VIN = vulvar intraepithelial neoplasia; STD = sexually transmitted disease.

Adapted from Crum, 1992, with permission.

Infection

HERPES SIMPLEX VIRUS

This infection has been shown to have a strong association with vulvar cancer in several studies. However, the association is more prominent when combined with other cofactors such as smoking (Madeleine, 1997). Thus, the presence of herpes simplex virus (HSV) alone in association with vulvar cancer as a causative factor for should not be considered conclusive.

HUMAN PAPILLOMAVIRUS

More recently, human papillomavirus (HPV) infection has been associated with vulvar cancer. For example, women positive for HPV serotype 16 show a higher risk of developing vulvar cancer. Moreover, HPV DNA from oncogenic HPV serotypes 16 and 18 has been isolated from carcinomatous and in situ lesions of the vulva (Ansink, 1994; Downey, 1988). However, there are stronger correlations between in situ vulvar lesions and HPV than with frankly invasive lesions and viral infection (Hildesheim, 1997). In addition, HPV DNA can be identified in 70 to 80 percent of intraepithelial lesions but is seen in only 10 to 50 percent of invasive lesions. These latter points support the idea that vulvar cancer develops along two distinct pathways, either with or without HPV.

Similar to HSV, the presence of HPV becomes a stronger risk for vulvar cancer when combined with other cofactors such as smoking and HSV infection (Madeleine, 1997). Women who have smoked and have a history of genital warts have a 35-fold increased risk for developing vulvar cancer compared with women without these factors (Brinton, 1990; Kirschner, 1995).

Immunosuppression

Chronic immunosuppression has been indirectly associated with vulvar cancer and is thought to contribute to persistent HPV and HSV infections. Specifically, vulvar cancer rates have been shown to be increased in women with HIV infection (Elit, 2005; Frisch,

2000).

Lichen Sclerosus

This chronic vulvar inflammatory disease has been particularly linked to the development of vulvar cancer and is discussed further in Chapter 4, Lichen Sclerosus. Although not validated as a causative or precursor lesion, current evidence suggests a correlative relationship between the two. Keratinocytes affected by lichen sclerosus show a proliferative phenotype and can exhibit markers of neoplastic progression. This suggests that lichen sclerosus may be a precursor lesion to invasive squamous vulvar cancer (Rolfe, 2001). Vulvar cancers that coexist with lichen sclerosus have been shown to develop in older women, predominate at or near the clitoris, and lack association with vulvar intraepithelial neoplasia (VIN).

Vulvar Intraepithelial Neoplasia

The natural history of VIN type 3 is unclear. On the one hand, the progression of VIN 3 to invasive cancer has been strongly suggested. Although most of VIN 3 lesions do not progress, several reports have demonstrated that in a small percentage of women older than 30 years, untreated lesions can progress to invasive cancer within a mean of 4 years (Jones, 2005; van Seters, 2005).

However, some cases of progression may reflect misdiagnosis. For example, a recent meta-analysis evaluated data from 3,322 women who were treated for VIN 3. Investigators found that occult carcinomas were diagnosed in the final pathology specimen in 3.2 percent of patients, and 3.3 percent of carcinomas were diagnosed during postoperative surveillance (van Seters, 2005). In addition, although recent reports have shown that the rate of VIN 3 has increased by 411 percent within the past 30 years, the rate of invasive squamous carcinoma of the vulva has risen a modest 20 percent (Judson, 2006). These observations suggest that aggressive treatment of preinvasive disease has not prevented the development of invasive tumors. Thus, the causes of in situ and invasive lesions may not be strongly related, or affected women may not have not yet reached the age at which invasive lesions are seen. An additional discussion of VIN is found in Chapter 29, Incidence.

SYMPTOMS

Most women with VIN and vulvar cancer present with pruritus and a visible lesion, although pain, bleeding, and ulceration also may be initial complaints (see Table 29-14). Most patients experience symptoms for weeks or months before diagnosis. Patient embarrassment and clinical unfamiliarity, as well as provider reluctance to fully evaluate symptoms, often adds to the delay.

A well-defined mass is not always present , especially in younger women with multifocal disease. Moreover, selecting the appropriate site for tissue sampling may be challenging. In such cases, multiple biopsies may be required during colposcopic examination of the vulva, termed *vulvoscopy* . Other clinical entities may present similarly and include preinvasive neoplasia, infection, chronic inflammatory disease, and granulomatous disease. Thus, the goal of evaluation should be to obtain an accurate and definitive pathologic diagnosis.

DIAGNOSIS

Lesion Evaluation

At the initiation of vulvoscopy, the vulva is soaked with 3% acetic acid for 5 minutes. This allows for adequate penetration into the keratin layer and aids identification of acetowhite areas and abnormal vascular patterns (see Chap. 29, Colposcopy). The entire vulva and perianal skin should be examined systematically. Lesions may be raised, ulcerated, pigmented, or warty, and biopsies of the most suspicious-appearing areas are obtained as described in Chapter 4, Vulvar Biopsy. Specimens removed with a Keyes punch forceps should be approximately 4 mm thick to include the surface epithelial lesion and the underlying stroma. This allows evaluation for the presence and depth of lesion invasion. Colposcopic examination of the cervix and vagina and careful examination of the perianal area are recommended to diagnose any synchronous or associated neoplasm of the lower genital tract. Women who have a well-defined mass should have a direct biopsy sent for pathologic evaluation.

Cancer Patient Evaluation

A complete evaluation of the woman with vulvar cancer requires assessment of the clinical extent of disease and coexisting medical

illnesses. Thus, detailed physical examination includes measurement of the primary tumor and evaluation of extension into other areas of the genitourinary system, the anal canal, the bony pelvis, and inguinal lymph nodes. At our institution, if a thorough physical is not possible secondary to patient discomfort or extent of disease, an examination under anesthesia is performed together with cystourethroscopy or proctosigmoidoscopy or both if suspicion of tumor invasion into the urethra, bladder, or anal canal is high.

Women with small tumors and clinically negative groin lymph nodes require few additional diagnostic studies other than those needed for surgical preparation. Additional radiologic studies such as computed tomographic (CT) scanning, magnetic resonance (MR) imaging, and intravenous pyelography are recommended in women with larger tumors to exclude local invasion, lymph node involvement, and metastatic disease. For some patients with advanced tumors, fine-needle aspiration biopsy from sites of suspected metastases may eliminate the need for surgical exploration.

Staging Systems

Currently, the International Federation of Gynecology and Obstetrics (FIGO) advocates surgically staging of a woman with vulvar cancer. In 1988, FIGO adopted a staging system that is based on a tumor, nodal, metastatic (TNM) classification. Thus, staging involves primary tumor resection to obtain tumor dimensions and dissection of superficial and deep inguinal lymph nodes for evaluation of tumor spread. In women with larger tumors or with metastatic inguinal lymph nodes, chest radiograph and either CT scanning or MR imaging of the abdomen and pelvis are also obtained preoperatively to determine the presence or absence of metastatic disease.

In 1995, FIGO instituted a subclassification of stage I tumors. In this group, stage IA lesions were 2 cm or smaller, were confined to the vulva or perineum, and displayed stromal invasion no greater than 1 mm. These lesions, termed *microinvasive cancers,* reflect a subpopulation in which the risk of inguinal metastasis is negligible (Binder, 1990; Donaldson, 1981; Hacker, 1984). The remainder of stage I lesions, classified as stage IB, are lesions of equivalent external dimensions but with stromal invasion greater than 1 mm (Table 31-3).

Table 31-3 FIGO Staging of Invasive Cancer of the Vulva

Stage 0	
Tis	Carcinoma in situ, intraepithelial carcinoma
Stage I	
T1 N0 M0	Tumor confined to the vulva and/or perineum, 2 cm or less in greatest dimension (no nodal metastasis)
	Stage IA Lesions 2 cm or less in size confined to the vulva or perineum and with stromal invasion no greater than 1.0 mm[a] (no nodal metastasis)
	Stage IB Lesions 2 cm or less in size confined to the vulva or perineum and with stromal invasion greater than 1.0 mm (no nodal metastasis)
Stage II	
T2 N0 M0	Tumor confined to the vulva and/or perineum, more than 2 cm in greatest dimension (no nodal metastasis)
Stage III	
T3 N0 M0	Tumor any size with
T1 N1 M0	(1) Adjacent spread to the lower urethra and/or the vagina or the anus, and/or
T2 N1 M0	(2) Unilateral regional lymph node metastasis

Stage IVA	
T1 N2 M0	Tumor invades any of the following: upper urethra, bladder, mucosa, rectal mucosa, pelvic bone, and/or bilateral regional node metastasis
T2 N2 M0	
T3 N2 M0	
T4 Any N M0	
Stage IVB	
Any T Any N M1	Any distant metastasis including pelvic lymph nodes

[a] The depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

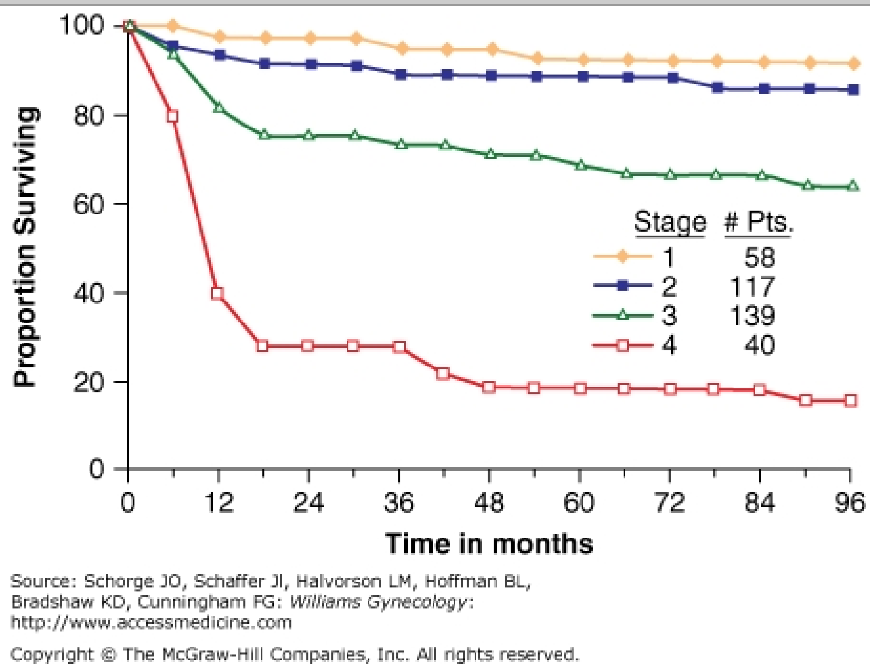
PROGNOSIS AND PROGNOSTIC FACTORS

The overall survival rates of women with squamous cell carcinoma of the vulva are excellent. Five-year survival rates of 80 to 90 percent are reported routinely for stage I and II disease. As anticipated, survival rates for higher stages are poorer. Rates of 48 percent for stage III and 15 percent for stage IV have been noted (Fig. 31-3). Numerous studies indicate that tumor stage, especially lymph node involvement; tumor thickness; location on the vulva; lymphatic vascular space involvement (LVSI); and histologic differentiation are all important prognostic factors for women with vulvar cancer.

FIGURE 31-3



Survival curves of women with invasive vulvar cancer grouped by FIGO stage. *(From Hoskins, 2000, with permission.)*

Lymph Node Metastasis

Lymph node metastasis is the single most important prognostic factor in vulvar cancer. The presence of inguinal node metastasis reduces long-term survival by 50 percent (Farias-Eisner, 1994; Figge, 1985). Among patients who have inguinal lymph node metastasis, factors that further delineate a poorer prognosis include bilateral involvement, extracapsular invasion, and increased dimension of lymph node metastasis if only one node is involved.

Nodal status is determined by surgical resection and pathologic evaluation. Independent predictors that increase the risk for nodal metastasis include less tumor differentiation; suspicious, fixed, or ulcerated nodes; and presence of lymphatic vascular space involvement (LVSI), older age, and increasing tumor thickness. Lesion size and location, however, are not associated factors (Homesley, 1993).

Tumor thickness is measured from the overlying surface epithelium to the deepest point of invasion, as specified by the International Society of Gynecological Pathologists, the World Health Organization, and FIGO (Creasman, 1995; Kalnicki, 1987; Scully, 1994) (Fig. 31-4). However, if a lesion is keratinized, then lesion thickness is measured from the granular layer to the greatest depth of tumor invasion. Tumors with a thickness of less than 1 mm carry little or no risk of groin metastasis, and increasing rates of metastasis are associated increasing thickness.

FIGURE 31-4

Histologic measurement of invasive vulvar cancers. **A.** Depth of invasion is measured from the junction between the epithelium and stroma of the most superficial dermal papilla to the greatest depth of tumor invasion. **B.** If a lesion is nonkeratinized, lesion thickness is measured from the lesion surface to the greatest depth of tumor invasion. **C.** If a lesion is keratinized, lesion thickness is measured from the granular layer to the greatest depth of tumor invasion. *(From Hoskins, 2000, with permission.)*

Surgical Margins

The risk of local recurrence is also related to surgical margin adequacy. A study by Heaps and co-workers (1990) showed that a 1-cm tumor-free surgical margin results in a high rate of local control, whereas margins less than 8 mm are associated with a 50-percent chance of recurrence. Although obtaining adequate margins may reduce the rate of vulvar cancer recurrence significantly, there is no evidence that simply taking wider margins will prevent local recurrences. Most recurrences owing to "residual" tumor

occur within a period of 2 years of primary therapy. Local recurrences seen after 2 years are more likely to be new tumors. Prevention of these late recurrences is less likely to be influenced by extending margins beyond 1 cm.

Lymphatic Vascular Space Invasion

Lymphatic vascular space invasion (LVSI) and association of a tumor with VIN 2 or 3 also predict early disease recurrence (Preti, 2005). For example, squamous cell carcinoma of the vulva with LVSI is associated with a higher frequency of lymph node metastasis and a lower overall 5-year survival rate (Hoskins, 2000).

Tumor Growth Pattern

Invasive vulvar cancer has two predominant growth patterns: moderately to poorly differentiated squamous cell carcinoma and keratinizing squamous carcinoma. Moderately to poorly differentiated carcinoma is frequently associated with HPV nuclei and sheets of immature neoplastic cells with a high nuclear:cytoplasmic ratio. There is a tendency for cohesive growth and a loss of cell polarity with a tendency to form irregular interconnecting sheets of tumor cells. These tumors are often (but not invariably) associated with HPV and VIN.

In contrast, keratinizing squamous carcinomas exhibit conspicuous maturation and keratinization. The basal cells appear to show mild to moderate atypia, with reduced atypia in the mature cells. These tumors fall into two general subcategories. The first consists of tumors organized into cohesive-appearing nests with a tendency toward blunt invasion intermixed with focal frank invasion. The second consists of tumors that are less well organized and invade the stroma with branching tongues and separate small cohesive units of well-differentiated tumor cells. These tumors are frequently associated with differentiated VIN and inflammatory dermatoses and often are HPV-negative (Crum, 2006).

Other patterns of growth invasion that are seen occasionally include verrucous carcinoma, papillary squamous carcinoma, and spindle cell squamous carcinoma. These patterns of growth are rare.

TREATMENT

Surgical Procedures

Procedures in the treatment of invasive vulvar neoplasia include wide local excision, radical partial vulvectomy, and radical complete vulvectomy, and each is described below (Fig. 31-5). Lymphadenectomy may accompany these procedures and typically includes excision of the deep and superficial inguinal lymph nodes (see Fig. 38-29). In certain cases, pelvic lymph nodes also may be excised.

Types of vulvectomy used in the treatment of vulvar cancer. **A.** En bloc radical vulvectomy with bilateral inguinal lymphadenectomy. **B.** Radical complete vulvectomy with bilateral inguinal lymphadenectomy. **C.** Radical partial vulvectomy with ipsilateral inguinal lymphadenectomy.

In contrast, the term *skinning vulvectomy* refers to removal of only the skin and superficial subcutaneous tissue. This surgery plays no role in the treatment of invasive vulvar cancer but may be used in noninvasive disease such as cases with widespread multifocal VIN 3 (see Section 43-25, Skinning Vulvectomy).

Microinvasive Tumors

Most women with microinvasive stage IA tumors tend to be younger and have multifocal disease associated with HPV. For curative resection, these patients can undergo *wide local excision,* also termed *simple partial vulvectomy,* to obtain 1- to 2-cm surgical margins around the lesion with dissection down to the superficial fascia of the urogenital diaphragm (see Fig. 38-28). Lymphadenectomy is not indicated for these very low-risk patients.

Early-Stage Vulvar Cancers

RADICAL VULVECTOMY

Women with stage IB and II vulvar cancers and a few stage III resectable vulvar cancers require radical resection of the primary tumor (Fig. 31-6).

FIGURE 31-6

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of invasive vulvar cancer. The lesion seen involves the labia minora bilaterally, urethral orifice, anterior lower vagina, and abuts the clitoris. *(Courtesy of Drs. David Miller and Jayanthi Lea.)*

An en bloc total *radical vulvectomy* involves excision of vulvar tissue between the labiocrural folds, from the perineal body to the superior border of the mons pubis. Dissection is carried downward to the level of the *perineal membrane,* which previously was termed the *deep fascia of the urogenital diaphragm* (see Chap. 38, Perineal Membrane). Conceptually, the rationale behind radical en bloc "butterfly" resection is to excise three areasâ€”the vulvar lesion, the superficial and deep inguinal lymph nodes, and the lymphatics in betweenâ€”to remove all possible "cancer-infiltrated" tissues. Accordingly, the incision includes the inguinal regions to allow lymphadenectomy of the deep and superficial inguinal lymph nodes with transposition of the sartorius muscle. The intent of resection is to obtain clear surgical margins with resulting long-term survival rates of 80 to 90 percent.

However, this approach often removes large pieces of healthy tissue and results in severe perineal disfuguration for a sometimes small, localized vulvar lesion. In addition, long hospital stays and high immediate- and long-term morbidities are common.

Although associated with improved survival, this extensive procedure and the need for complete lymphadenectomy during staging have been reevaluated over the years. Careful histologic review of the skin that bridges the vulva and groins and recent lymph node radiolabeling studies have lead to a more conservative approach to vulvar cancer surgery discussed below.

RADICAL PARTIAL VULVECTOMY

Currently, modified surgical resection of a primary tumor, termed *radical partial vulvectomy,* aims to obtain clear surgical margins of 1 to 2 cm around the tumor, remove all tissue beneath this margin down to the perineal membrane, but avoid excision of other healthy tissues (see Section 43-22, Radical Partial Vulvectomy). This approach often allows preservation of function and significantly less morbidity. Various names have been used to describe this procedure and include *radical local excision, radical wide excision, radical hemivulvectomy,* and *modified vulvectomy.* Inguinal lymphadenectomy is performed using small, separate incisions below and parallel to the inguinal ligament.

RADICAL COMPLETE VULVECTOMY

In a *radical complete vulvectomy* , the entire vulva is removed. The borders of resection are generally the mons pubis superiorly, the perineal body inferiorly, and the labiocrural folds laterally. The clitoris is removed, and the deep margin is extended to the perineal membrane (see Section 43-23, Radical Complete Vulvectomy). This procedure is rarely used in early-stage vulvar cancers.

LYMPHADENECTOMY

The decision to remove superficial and deep inguinal lymph nodes is debatable. In 1979, DiSaia and colleagues reported on reduced excision around the central tumor and selective removal of the superficial nodes. Deep inguinal nodes were removed only if the superficial nodes were positive for metastatic disease. Unfortunately, leaving deep inguinal nodes was associated with nodal recurrences in 5 percent of patients long before the appearance of a central recurrence (Burke, 1995; Stehman, 1992, 1996.)

A modified approach to superficial and deep inguinal lymphadenectomy is performed by preserving the fascia lata. The saphenous vein is also spared in most women. Deep nodes are removed medial to the femoral vein within the opening of the fossa ovalis (Bell, 2000). This procedure has been shown to have comparable recurrence rates to those obtained with classic groin dissection in which fascia lata is removed and the sartorius muscle is transposed over the femoral vessels (Bell, 2000; Hacker, 1983). Complications of wound breakdown, infection, and lymphedema are decreased significantly with this conservative approach (Table 31-4). Steps of lymphadenectomy are described and illustrated in Section 43-24, Inguinal Lymphadenectomy.

Table 31-4 Postoperative Complications

Complication	No. of Events	Percent of Groins
Lymphedema	13	14.0
Lymphocele	11	11.8
Groin infection	7	7.5
Groin necrosis	2	2.2
Groin separation	7	7.5

SENTINEL NODE BIOPSY

Recent developments in the management of other malignancies such as carcinoma of the breast suggest that selective dissection of a solitary node or nodes, termed *sentinel node biopsy,* may reduce morbidity and yet adequately assess nodal involvement. The first lymph node to receive lymphatic drainage from the tumor site, termed the *sentinel lymph node,* is considered the first site of malignant lymphatic spread. Therefore, a sentinel lymph node devoid of disease implies the absence of lymph node metastases in the entire draining basin. At present, the Gynecologic Oncology Group (GOG) is conducting a multicenter trial to evaluate the benefit of sentinel node biopsy for vulvar cancer.

Although sentinel node biopsy may decrease postoperative morbidity, clinicians should realize that many women may select procedures with increased morbidity, if they offer a lower cancer recurrence risk. A recent survey in a group of vulvar cancer survivors indicated that although many suffered from cellulitis or severe lymphedema, 60 percent preferred formal superficial and deep inguinal lymphadenectomy to a 5-percent false-negative rate associated with minimally invasive sentinel node procedures.

Node-Positive Cancers

An optimal strategy to manage patients with node-positive vulva cancer is yet to be defined. Several options are available for women who are found to have positive nodes on an ipsilateral groin dissection. One approach is to perform a contralateral inguinal femoral lymphadenectomy. Postoperative irradiation is given to groin and pelvis of the ipsilateral side and contraleral side only if more than one microscopic node is identified. The alternative approach is to limit the dissection to the ipsilateral groin and add postoperative irradiation.

The GOG has established evidence that adjunctive radiation improves survival in patients with positive groin nodes (Homesley, 1986). Two major poor prognostic factors were clinically suspicious or fixed ulcerated groin nodes and two or more positive groin nodes. However, for women with only one positive groin node, survival following radiation does not appear improved compared with lymphadenectomy alone.

CHEMORADIATION

Successful use of chemoradiation for certain cervical cancers suggests that concurrent chemotherapy with radiation in women with vulvar cancer also may improve survival. The GOG is currently conducting a randomized study exploring concurrent chemotherapy in the form of weekly cisplatin with adjuvant postoperative radiation therapy to the inguinopelvic regions to improve inguinopelvic control and survival.

Stage III and IV Cancers

By definition, stage III and IVA vulvar cancers involve adjacent mucosal structures or inguinal lymph nodes. A few advanced-stage vulvar cancers can be treated with primary surgery in the form of a radical partial vulvectomy, adhering to the principle of radical resection to the perineal membrane and obtaining 1- to 2-cm margins. However, most advanced-stage vulvar cancers require resection using some variations of pelvic exenteration and radical vulvectomy.

Recent therapeutic efforts, however, have focused on treatment modalities that combine radiation, chemotherapy, and less aggressive surgery. Phase II studies have demonstrated that primary chemoradiation reduced the necessity of radical surgery or exenteration significantly in patients with advanced vulvar cancer (Moore, 1998). In cases in which a patient does not have fixed groin nodes, pretreatment inguinofemoral lymph node dissection may help determine the need for groin irradiation. Women with negative groin lymph nodes receive radiation therapy to the vulva. All patients with grossly or histologically positive nodes receive radiation therapy to the inguinofemoral and lower pelvic lymph nodes at the discretion of the treating physician.

Although occasional cures have been described for patients with stage IVB disease, most treatment of such patients should be considered palliative.

SURVEILLANCE

Completing primary treatment, all patients receive a thorough physical examination, including a node survey and pelvic examination, every 3 months for the first 3 years. Surveillance examinations then are scheduled every 6 months for the next 2 years. Five years after primary treatment, disease-free patients may be seen annually. Vulvoscopy and biopsies are performed if areas of concern are noted during history or physical examination. Radiologic imaging and biopsies to diagnose possible tumor recurrence are performed as indicated.

RECURRENT DISEASE

In a patient who presents with a suspected recurrence, a careful evaluation should be completed to define the extent of disease. For local vulvar recurrences, surgery is preferred. Typically, a radical partial vulvectomy is performed for treatment of a local recurrence not involving the urethra or perineum. If needed, flap reconstruction of a surgical defect can be completed. For large central recurrences involving the urethra, vagina, or rectum, a total pelvic exenteration may be required. To maintain sexual function, vaginal reconstruction can be completed at the time of surgery or after a short postoperative interval.

For all these procedures, high postoperative morbidity has been reported, and women must be in overall good health to undergo these procedures. For previously irradiated patients who present with gross recurrence, surgery is not a treatment option because of the extraordinary high incidence of operative morbidities and poor prognosis. For patients without prior radiation treatment who refuse surgery or those who are not surgical candidates, external-beam radiation combined with interstitial brachytherapy can be used (see Chap. 28, External Radiation Therapy).

After surgical treatment of local recurrence, if surgical margins are positive for microscopic invasion or metastases are present in the inguinal lymph nodes, then external-beam radiation may have some benefit in those who have not received radiotherapy before. Inguinal lymph node recurrences, however, offer a dismal prognosis. Few of these women are alive at the end of the first

year following diagnosis.

Palliative chemotherapy can be offered to patients with pelvic or distant metastases. However, there are few data to indicate that chemotherapy provides an effective palliative intervention. Only doxorubicin and bleomycin appear to have reproducible activity as single agents. Combination chemotherapy including cisplatin also has shown to have modest activity in recurrent vulvar cancers (Cunningham, 1997; Moore, 1998).

MANAGEMENT DURING PREGNANCY

Squamous cell cancer of the vulva diagnosed and treated surgically during pregnancy is rare, and an incidence of 1 in 20,000 deliveries has been reported (DiSaia, 1997). Nevertheless, all suspicious lesions should be examined and biopsied, even during pregnancy, to prevent a delayed diagnosis.

Radical partial vulvectomy and bilateral groin dissection can be performed when indicated after the eighteenth week of gestation. When diagnosed during the third trimester, lesions may be removed by wide local excision, and definitive surgery can be postponed until the postpartum period. In women in whom diagnosis is not made until delivery, definitive surgery should be started as soon as deemed appropriate by the treating physician.

The mode of delivery is left to the discretion of the obstetrician and is heavily influenced by the state of the postoperative vulva. In instances of vaginal stenosis, significant fibrosis, or tumor involvement, a cesarean delivery is recommended.

MELANOMA

Melanoma of the vulva is the second most common malignancy arising within the vulva. Vulvar melanoma is a disease of the elderly, and its incidence peaks in the fifth to eighth decades of life (Piura, 1992; Podratz, 1983). It develops more commonly among Caucasians than among African-American, Asian, or other more heavily pigmented races (Evans, 1994; Franklin, 1991; Jaramillo, 1985; Piura, 1992; Ronan, 1990).

Malignant vulvar melanoma will arise most commonly from the labia minora, labia majora, or clitoris (Ariel, 1981; Blessing, 1991; Moore, 1998; Piura, 1992; Woolcott, 1988) (Fig. 31-7). Similarly, a variety of benign pigmented lesions including lentigo simplex, vulvar melanosis, acanthosis nigricans, seborrheic keratosis, and junctional, compound, intradermal, or dysplastic nevi, also may be found in these areas (see Chap. 4, Lesions of Pigmentation). In addition, pigmented vulvar neoplasia may include VIN, squamous carcinoma, and Paget disease. Thus, tissue sampling is necessary, and immunohistochemical studies and electron microscopy may help to clarify the diagnosis. Three histologic subtypes of vulvar melanoma have been described: superficial spreading melanoma (SS), nodular melanoma (NM), and acral lentiginous melanoma (AL).

FIGURE 31-7

Vulvar melanomas have been staged by a variety of microstaging systems, including the Chung, the Clark, and the Breslow systems (Table 31-5). The Clark system of staging cutaneous melanomas is based on depth of invasion. Agreeing that depth of invasion is important, Breslow published an alternative list of prognostic indicators but added tumor size and used tumor thickness as the most significant measures. Both the Clark and the Breslow systems have been found to correlate with prognosis in patients with cutaneous melanoma.

Table 31-5 FIGO Staging for Vulvar Melanoma	
FIGO Stage	**Description**
	Primary tumor cannot be assessed
	No evidence of primary tumor
0	Carcinoma in situ (preinvasive carcinoma)
I	Tumor confined to vulva or vulva and perineum, 2 cm or less in greatest dimension
IA	Tumor confined to vulva or vulva and perineum, 2 cm or less in greatest dimension and with stromal invasion no greater than 1.0 mm
IB	Tumor confined to vulva or vulva and perineum, 2 cm or less in greatest dimension and with stromal invasion greater than 1.0 mm
II	Tumor confined to the vulva or vulva and perineum, more than 2 cm in greatest dimension
III	Tumor invades any of the following: lower urethra, vagina, anus
IV	
IVA	Tumor invades bladder mucosa, rectal mucosa, or upper urethral mucosa or is fixed to bone
IVB	Any distant metastasis including pelvic lymph nodes

From Irvin, 2001, with permission.

There are no prospective data from randomized clinical trials evaluating the ideal extent of surgical margins in women with vulvar melanoma. At our institution, we recommend that patients undergo a radical partial vulvectomy with a 2-cm margin for lesions that are 1 to 4 mm thick and a 1-cm margin if lesion thickness is less than 1 mm.

The incidence of occult inguinal lymph nodes is less than 5 percent for thin melanomas (<1 mm) and greater than 70 percent for thick lesions (>4 mm) (Hoskins, 2000). Accordingly, a minimally invasive evaluation of the inguinal lymph nodes, such as sentinel node biopsy, may be reasonable for patients who have tumor thicknesses between 1 and 4 mm. However, this method of evaluation remains a topic of controversy in the management of melanoma. Previous retrospective studies in cutaneous melanoma have confirmed and disproved the superiority of elective regional node dissection versus sentinel lymph node biopsy in patients with intermediate-thickness melanoma (0.76 to 4.0 mm) (Balch, 1982; Milton, 1982; Reintgen, 1983). The appeal of the sentinel node biopsy is based on the possibility of sparing patients with no sentinel node disease the morbidity of a full groin node dissection.

In a GOG study examining the management of vulvar melanoma, the authors were unable to reach a conclusion relative to the benefit of elective lymph node dissection in these patients (Phillips, 1994). Patients with lesions thicker than 4 mm may undergo an elective lymphadenectomy.

Recent trials have suggested that adjuvant therapy may be of benefit in preventing recurrence in certain patients with cutaneous melanoma involving other body surfaces. Specifically, high-dose adjuvant interferon-alpha has been shown to increase both progression-free and overall survival rates in patients with cutaneous melanoma. However, given the small number of women with vulvar melanoma, no trials have yet evaluated the benefit of adjuvant therapy in these women. Moreover, tolerability of the interferon regimen has remained a barrier to patient acceptance.

In general, vulvar melanomas carry a poor prognosis and show a tendency to recur locally and develop distant metastases through hematogenous dissemination. Deaths from vulvar melanoma result more commonly from the effects of widespread metastatic disease, most commonly involving the lungs, liver, or brain. Women diagnosed with vulvar melanoma have a median survival of 61 months. The 5-year survival rate is 60 percent and at 10 years, there is a 50-percent adjusted survival rate (Irvin, 2001). African-American race and increasing age are both significant independent predictors of decreased survival (Irvin, 2001).

BASAL CELL CARCINOMA

Basal cell carcinoma (BCC) of the vulva accounts for less than 2 percent of all vulvar cancers and is found most commonly in elderly women (DiSaia, 1997). In the vulvar area, BCC is characterized by poor pigmentation, pruritus, and a clinical appearance often mimicking other dermatopathologies such as eczema, psoriasis, or intertrigo. As a result, correct diagnosis often is delayed and typically follows treatment for other presumed inflammatory or infectious dermatoses.

Although ultraviolet radiation is thought to be the primary risk factor for BCC on sun-exposed areas, its development on areas protected from sunlight raises the possibility of other, yet undefined etiologic agents. The literature suggests that local trauma and advancing age may contribute to the development of BCC in these sites (LeSueur, 2003; Wermuth, 1970).

BCC should be removed by wide local excision using a minimum surgical margin of 1 cm. Lymphatic or distant spread is rare, However, local recurrences may occur, particularly in tumors removed with suboptimal resection margins.

VULVAR SARCOMA

Sarcoma of the vulva is rare. Leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, and malignant rhabdoid tumor are some of the more commonly encountered histologic types. Tumors typically develop as isolated masses in the labia majora, clitoris, or Bartholin gland.

Unlike in squamous cell carcinoma of the vulva, the age of affected women is significantly broader and varies among histologic types. There are no large prospective series reporting the management of vulvar sarcoma, although recommended treatment for most types is primary surgery followed by adjuvant radiation or chemotherapy or both.

BARTHOLIN GLAND ADENOCARCINOMA

Adenocarcinoma of the Bartholin gland accounts for 1 percent of vulvar malignancies, and its incidence peaks in women in their midsixties. Soft, distensible tissue surrounds these tumors, and they may reach considerable size before women develop symptoms. Dyspareunia is a common first complaint.

Bartholin gland infections decrease with advancing age. Thus, Bartholin gland enlargement in a postmenopausal woman should prompt biopsy to exclude malignancy. Solid masses may require fine-needle aspiration to establish a diagnosis. Cystic masses should be drained and suspicious regions of the cyst wall biopsied.

Bartholin gland adenocarcinomas have a tendency to spread into the ischiorectal fossa and can have a propensity for lymphatic spread into the inguinal nodes and pelvic nodes. Therapy includes radical partial vulvectomy with inguinal lymphadenectomy.

VULVAR PAGET DISEASE

Vulvar Paget disease is a heterogeneous group of intraepithelial neoplasias that present similarly as eczematoid, red, weeping areas on the vulva. They often are localized to the labia majora, perineal body, or clitoral area. This disease typically develops in older Caucasian women and accounts for approximately 2 percent of all vulvar tumors. Vulvar Paget disease is accompanied by invasive adenocarcinoma in 10 to 20 percent of cases (Hoskins, 2000). In addition, 20 to 30 percent of patients will have or will later develop an adenocarcinoma at another nonvulvar location.

A histologic classification proposed by Williamson and Brown includes: (1) primary vulvar cutaneous Paget disease, (2) Paget disease as an extension of an associated adjacent primary cancer such vulvar, anal, or rectal cancer, and (3) Paget disease as an extension of transitional cell carcinoma of the bladder or urethra. The histologic differentiation of the types of Paget disease is of utmost importance because the specific diagnosis has significant influence on the treatment provided.

Primary cutaneous vulvar Paget disease displays slow growth. Thus, with invasion of 1 mm or less, there is little risk for recurrence. These lesions can be treated with a wide local excision. However, if invasive disease is suspected, a radical partial vulvectomy is warranted. Screening and surveillance for tumors at nongynecologic sites should be considered for all patients with Paget disease.

VAGINAL CANCER: INTRODUCTION

Primary vaginal carcinoma is rare and comprises only 1 to 2 percent of all gynecologic malignancies (Creasman, 1998; Pride, 1977). This low incidence reflects the infrequency at which primary carcinoma arises in the vagina as well as the strict criteria for its diagnosis. According to International Federation of Gynecology and Obstetrics (FIGO) staging criteria, a lesion in the vagina that involves adjacent organs such as the cervix or vulva is, by convention, deemed primary cervical or vulvar, respectively (Pecorelli, 1999). The most common histologic type of primary vaginal cancer is squamous cell carcinoma, followed by adenocarcinoma (Fig. 32-1) (Platz, 1995).

ANATOMY

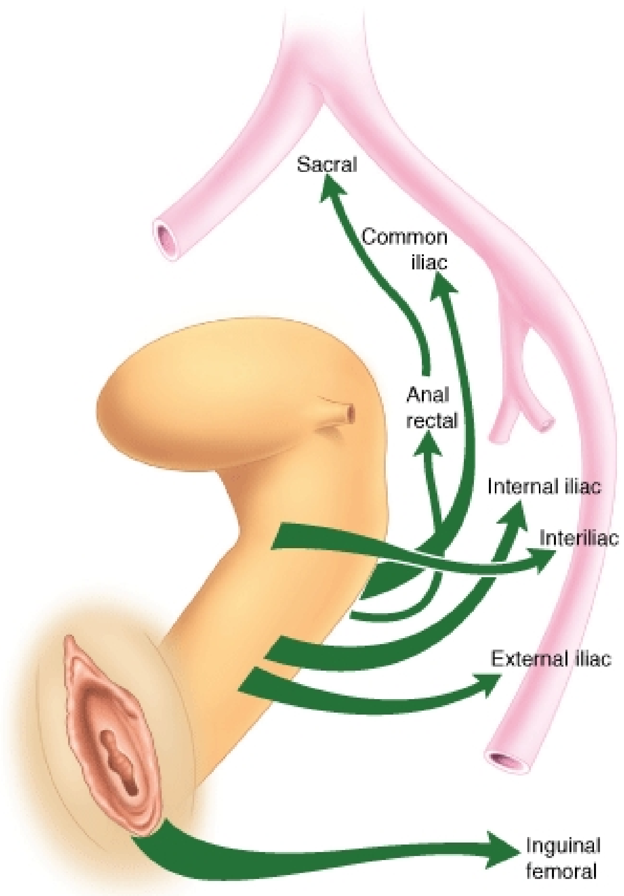
Vaginal Epithelium

Embryologically, both the mÃ¼llerian ducts and the urogenital sinus contribute to form the vagina (see Fig. 18-4). Early in fetal development, the caudal ends of the mÃ¼llerian ducts fuse to form the uterovaginal canal, which is lined by columnar epithelium. Subsequently, squamous cells from the urogenital sinus migrate along the uterovaginal canal and replace this original columnar epithelium. These squamous cells stratify, and the vagina begins to mature and thicken (Zaino, 2002). Underlying this epithelium, muscularis and adventitial layers are found (see Fig. 24-5).

Vascular and Lymphatic Supply

Local extension and lymphatic invasion are common patterns of vaginal cancer spread. The lymphatic channels that drain the vagina form extensive, complex, and variable anastamoses (Fig. 32-2). As a result, any node in the pelvis, groin, or anorectal area may drain any part of the vagina (Zaino, 2002). However, the external, internal, and common iliac lymph nodes are the primary sites of vaginal lymphatic drainage. Alternatively, the posterior vagina may drain to the inferior gluteal, presacral, or perirectal lymph nodes, and the distal third of the vagina may drain to the superficial and deep inguinal lymph nodes (Frank, 2005).

FIGURE 32-2



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Lymphatic drainage patterns of the vagina. (From Stenchever, 2001, with permission.)

Hematogenous spread of vaginal cancer is less frequent, and venous drainage consists of the uterine, pudendal, and rectal veins, which drain into the internal iliac vein. Arterial blood supply to the vagina comes primarily from branches of the internal iliac artery, which include the uterine, vaginal, middle rectal, and internal pudendal arteries (see Fig. 38-22).

SQUAMOUS CELL CARCINOMA

Incidence

Squamous cell carcinoma accounts for 70 to 80 percent of all primary vaginal cancers (Beller, 2003; Platz, 1995). Its incidence is 0.42 per 100,000 in white women and 0.93 per 100,000 in black women. This has not changed significantly in the last 30 years (Cramer, 1974; Platz, 1995).

Risks

As with other cancers of the lower reproductive tract, the human papillomavirus (HPV) has been closely linked with squamous cell vaginal cancer (see Chap. 29, Human Papillomavirus). For example, Daling and colleagues (2002) analyzed results from a case-control study of 156 women with squamous cell carcinoma in situ or invasive vaginal carcinoma. Human papillomavirus DNA was detected in 82 percent of the in situ lesions and 64 percent of the invasive tumors. Specifically, antibodies to HPV serotypes 16 and 18 were identified in more than 50 percent of all patients. Because of this association with HPV infection, vaginal in situ and invasive squamous cell carcinoma share risk factors similar to cervical cancer, which include five or more lifetime sexual partners, early age at first intercourse, and current cigarette smoking.

DIAGNOSIS

Vaginal bleeding is the most common complaint associated with vaginal cancer, although pelvic pain and vaginal discharge also may be noted. Less frequently, lesions involving the anterior vaginal wall may lead to dysuria, hematuria, or urgency. Alternatively, constipation may result from those of the posterior wall. Most vaginal cancers develop in the upper third of the vagina. Moreover, of those with cancers, women who had a prior hysterectomy are significantly more likely to have lesions in the upper vagina (70 percent) than those without prior hysterectomy (36 percent) (Chyle, 1996).

During pelvic evaluation in all women, the vagina should be inspected as the speculum is being inserted or removed. If a gross lesion is found, vaginal cancer usually can be diagnosed following punch biopsy in the office. Biopsy may be obtained with a Tischler biopsy forceps, (see Fig. 29-11). An Emmett hook may be used to elevate and stabilize vaginal tissue during biopsy. If a gross lesion is not detectable, vaginoscopy can be useful to direct biopsies, as described in Chapter 29, Vaginal Colposcopy. Bimanual examination can assist in determining the tumor size, and rectovaginal examination is especially important for posterior wall lesions.

Once cancer is diagnosed, no specific laboratory testing other than that used generally for preoperative preparation, such as complete blood count and serum chemistry panel, is required. Computed tomographic (CT) scanning can delineate the size and extent of many tumors (Fig. 32-3). However, if the extent of cancer expansion is unclear, magnetic resonance (MR) imaging is the most useful imaging tool available to visualize the vagina. Proctosigmoidoscopy to a depth of at least 15 cm can be helpful to detect local bowel invasion, whereas cystourethroscopy should be performed in the presence of anterior tumors to exclude bladder or urethral involvement.

Computed tomography (CT) scan reveals size and extent of vaginal mass (arrow). (*Courtesy of Dr. Betty Chen.*)

STAGING AND CLASSIFICATION

Staging of vaginal cancer is similar to that for cervical cancer and is completed clinically by physical examination and with the assistance of cystourethroscopy, proctosigmoidoscopy, and chest radiography (Table 32-1). Both CT scanning and MR imaging may be useful in treatment planning but are not used to determine disease stage.

CT = computed tomographic; MR = magnetic resonance.

[a] Useful for treatment planning but not used to assign FIGO stage.

PROGNOSIS

The prognosis of squamous cell carcinoma of the vagina has improved since the 1950s. At that time, Palmer published a review of 992 cases, which showed a dismal 5-year survival rate of only 18 percent. Advances in radiation technology and earlier diagnosis

are largely responsible for the improved 5-year survival rate. Currently, this rate ranges from 45 to 60 percent for all stages (Frank, 2005; Hellman, 2006).

The prognosis of squamous cell carcinoma of the vagina depends primarily on FIGO stage (Fig. 32-4 and Table 32-2) (Frank, 2005; Peters, 1985b). The 5-year disease-specific survival rate is 85 percent for women with stage I disease, 78 percent for those with stage II, and 58 percent for those with stage III or IVA (Fig. 32-5).

Disease-specific survival by disease stage for 193 women with squamous cell carcinoma of the vagina. Women with stage III and IVA disease were combined for the analysis because of the small number of patients (n = 7) with stage IVA disease. Numbers in parentheses indicate the number of patients at risk 5 or 10 years after treatment. (*From Frank, 2005, with permision.*)

Table 32-2 FIGO Staging Classification of Vaginal Cancer

Stage	Definition
0	Carcinoma in situ, intraepithelial neoplasia
I	The carcinoma is limited to the vaginal wall
II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall
III	The carcinoma has extended to the pelvic wall
IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Spread to distant organs

FIGO = International Federation of Gynecologic Oncologists.

TREATMENT

Owing to vaginal cancer's rarity, there is a paucity of prospective, randomized trials evaluating its treatment. Therefore, therapy is individualized and based on factors such as tumor type, stage, location, and size.

Stage I

Both surgery and radiotherapy are options for stage I disease. However, surgery is preferred for most if surgical margins negative for cancer can be achieved. A review of the National Cancer Data Base showed that women treated with surgery alone had a significantly improved 5-year survival rate compared with those treated with radiation (90 percent versus 63 percent) (Creasman, 1998). However, others have found no significant difference in disease-free survival rates at 5 years in women treated with surgery compared with radiation alone (Stock, 1995). Radiotherapy may be delivered by external beam or brachytherapy or both as described in Chapter 28, Radiation Therapy. Specifically, brachytherapy alone has been used successfully to treat small stage I lesions (Nori, 1983; Pempree, 1985; Perez, 1999; Reddy, 1991).

Stage II

Stage II disease is treated with either surgery or radiation at the discretion of the treating clinician. Stock and colleagues (1995) found a significant survival advantage at 5 years in those with stage II disease treated with surgery compared with those treated with radiation (62 percent versus 53 percent). Review of the National Cancer Data Base showed that the 5-year survival rate for women with stage II disease treated with surgery alone was 70 percent; with radiotherapy alone 57 percent; and with a combination of surgery and radiotherapy 58 percent (Creasman, 1998). However, other authors have found no survival advantage of surgery compared with radiotherapy in stage II disease (Davis, 1991; Rubin, 1985).

If radiation is to be administered, it is given most often as a combination of external beam radiation and brachytherapy. External beam radiation generally is given first, and depending on tumor response, brachytherapy is tailored to remaining disease. Radiation is recommended when it is felt that negative margins cannot be achieved with surgery owing to the anatomic location or size of the tumor or if a woman has medical comorbidities and is deemed not to be a surgical candidate.

Stage III and IV

For advanced disease, external beam radiation alone or a combination of this and brachytherapy usually is administered (Frank, 2005). Concurrent chemotherapy with cisplatin as a radiation adjunct is recommended (see Chap. 28, Combination of Ionizing Radiation and Chemotherapy).

Chemoradiation

Chemotherapy in combination with radiation treatment has been found to be superior to radiation alone for squamous cell carcinoma of the cervix in a number of prospective, randomized trials (Keys, 1999; Morris, 1999; Peters, 2000; Rose, 1999; Whitney, 1999). Although the numbers of women with vaginal cancer have been too small to make a prospective, randomized trial feasible, it is generally extrapolated that the addition of chemotherapy to radiation treatment would be beneficial in those with vaginal cancer as well. In a small series, it was found that the addition of concurrent chemotherapy allowed a 10 to 33 percent decrease in the total amount of radiation delivered (Dalrymple, 2004). Although the authors were not intending to show an improved survival with chemoradiation, they found that local control of tumor growth and survival rates were comparable with those who had received higher doses of radiation alone. Decreases in the total dose of radiation may lead to lower rates of vaginal stenosis and fistula formation.

Chemotherapy

In general, chemotherapy alone is ineffective in the treatment of vaginal cancer, although data supporting this are limited. The Gynecologic Oncology Group (GOG) performed a phase II trial evaluating cisplatin for advanced or recurrent cancer of the vagina in 26 patients. Only one woman with squamous cell carcinoma achieved a complete response. Five of 16 patients with squamous cell

carcinoma had stable disease, and 10 had progression of disease with cisplatin. From this it was concluded that single-agent cisplatin at that dose was ineffective for treatment of vaginal carcinoma (Thigpen, 1986). To date, this has been the only prospective, randomized trial evaluating chemotherapy alone in vaginal cancer.

Radiation Therapy

Radiation is delivered to the deep and superficial inguinal lymph nodes if biopsy reveals metastasis or prophylactically if the distal third of the vagina is involved. In a retrospective review, Perez and colleagues (1999) found that of 100 women who did not receive groin radiation, if disease was confined to the upper two-thirds of the vagina, then none developed groin metastases. However, if disease involved the lower third or extended throughout the length of the vagina and radiotherapy was not delivered, then groin metastases developed in 3 of 29 (10 percent) and in 1 of 20 patients, respectively.

SURVEILLANCE

Because treatment failures usually occur within 2 years of completion of the primary therapy, patients usually are followed every 3 months for the first 2 years and then every 6 months until 5 years (Pingley, 2000; Rubin, 1985). After 5 years following treatment, women can be seen annually. A Pap smear and pelvic examination with careful attention to the inguinal and scalene nodes are performed. Surveillance imaging with CT scanning or MR imaging is at the clinician's discretion.

RECURRENT DISEASE

Disease recurrence should be confirmed by biopsy if further treatment is planned. Therapeutic options in women with central pelvic recurrence who have had prior pelvic radiation are limited. Pelvic exenteration can be considered if a patient is psychologically and medically fit to undergo radical surgery with high morbidity. Moreover, it should be attempted only in those whose disease is limited to the central pelvis. Therefore, clinicians should be alert to the triad of sciatic pain, leg edema, and hydronephrosis, which is suggestive of pelvic sidewall disease. These women are not surgical candidates but can be managed with chemoradiation or with chemotherapy alone for women previously irradiated.

Survival after relapse is poor. In a review of 301 patients, 5-year survival was 20 percent for local recurrence and 4 percent for metastatic disease recurrence (Chyle, 1996).

SQUAMOUS CELL VAGINAL CANCER IN PREGNANCY

Squamous cell vaginal cancer in pregnancy is rare, and only 13 cases have been reported in the literature (Fujita, 2005). Women may be treated with surgical resection, radiation, chemoradiation, or a combination of these, and survival rates mirror those of nonpregnant women. Typically, treatment and timing of delivery must be tailored to the individual patient because there is limited evidence to support a general recommendation. Women may elect to terminate their pregnancies or effect delivery at the time of cancer diagnosis to begin treatment. However, this does not appear to improve survival rates. Alternatively, a woman may choose to continue her pregnancy, and most who do, undergo cesarean delivery.

VERRUCOUS CARCINOMA

Verrucous carcinomas of the vagina are an extremely rare variant of squamous cell carcinoma. Grossly, verrucous carcinoma is a warty and fungating mass that grows slowly, pushing into rather than invading contiguous structures (Fig. 32-6) (Isaacs, 1976). The diagnosis may be difficult to determine and may not be possible with a superficial biopsy. For this reason, multiple, large biopsies are recommended to avoid misdiagnosis and inadequate treatment.

FIGURE 32-6

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Verrucous carcinoma of the vagina. (*From Zaino, 2002, with permission.*)

Treatment requires surgical resection with either wide local excision for smaller lesions or radical surgery for larger tumors (Crowther, 1988). Verrucous carcinomas are resistant to radiotherapy and actually may transform to conventional squamous cell carcinoma after radiation (Zaino, 2002). Therefore, radiation treatment is contraindicated for these tumors.

Verrucous carcinoma has a tendency for local recurrence but rarely metastasizes to lymph nodes. This cancer may coexist with squamous cell carcinoma. When it does, it should be managed as a squamous cell carcinoma.

VAGINAL ADENOSIS- AND DES-RELATED TUMORS

Vaginal adenosis is a condition common in females exposed to diethylstilbestrol (DES) (see Chap. 18, Acquired Uterine Defects). *Adenosis* found in the vagina is defined as the presence of subepithelial glandular structures lined by mucinous columnar cells that resemble endocervical cells (Sandberg, 1965). These are residual glands of mÃ¼llerian origin. Clinically, adenosis appears as red granular spots or patches and does not stain following Lugol solution application.

Adenocarcinoma

Primary adenocarcinoma of the vagina is rare, comprising only 13 percent of all vaginal cancers (Platz, 1995). When the vagina is the primary site, it is believed to arise from adenosis. More commonly, vaginal adenocarcinoma is metastatic disease, typically from a lesion higher in the genital tract. Metastatic disease frequently arises from the endometrium, although it also may originate in the cervix or ovary (Saitoh, 2005). In addition, adenocarcinoma metastases from the breast, pancreas, kidney, and colon also have been identified in the vagina.

Treatment is similar to that for squamous cell carcinoma, and either surgery, radiation, or a combination of both can be used. Primary adenocarcinoma of the vagina is a more aggressive tumor than squamous cell carcinoma, and in one series of 30 patients, it was associated with greater than twice the local and metastatic relapse rates of squamous cell carcinoma (Chyle, 1996).

Clear Cell Adenocarcinoma

In 1971, clear cell adenocarcinoma of the vagina was linked initially to in utero exposure to DES (Fig. 32-7) (see Chap. 18, Acquired Uterine Defects). It is estimated that 1 to 4 million women used DES and that approximately 0.01 percent of females exposed in utero developed clear cell adenocarcinoma of the vagina (Melnick, 1987). Most DES-exposed patients with vaginal cancer were born between 1951 and 1953, when the drug was prescribed most frequently. The median age at diagnosis of vaginal clear cell carcinoma in the United States is 19 years.

FIGURE 32-7

Photograph of a cervix in a patient with in utero DES exposure. A vaginal shelf, often described as a vaginal hood, is seen above the cervix **(arrow)** . (*Courtesy of Dr. Claudia Werner* .)

However, in the Netherlands, a bimodal distribution of vaginal clear cell carcinoma has been shownâ€”the first peak occurring with a mean age of 26 years and the second at 71 years. The younger group all had been exposed in utero to DES, whereas the older group, born before 1947, had not been exposed (Hanselaar, 1997). It remains to be seen if the incidence of vaginal clear cell carcinoma will rise as the DES-exposed population ages.

Treatment is similar to that for squamous cell carcinoma of the vagina. Five-year survival rates for 219 patients with stage I

disease was 92 percent and was equivalent regardless of mode of therapy (Senekjian, 1987). The reported 5-year survival for 76 patients with stage II disease was 83 percent (Senekjian, 1988).

EMBRYONAL RHABDOMYOSARCOMA (SARCOMA BOTRYOIDES)

Embryonal rhabdomyosarcoma is the most common malignancy of the vagina in infants and children. Most are of the subtype sarcoma botryoides. This rare tumor develops almost exclusively in girls aged younger than 5 years, although vaginal and cervical sarcoma botryoides have been report in females aged 15 to 20 years (Copeland, 1985a).

In infants and children, sarcoma botryoides usually is found in the vagina; in reproductive-aged women, within the cervix; and after menopause, within the uterus. Its name, derived from the Greek word *botrys,* which means "bunch of grapes", describes its appearance (Fig. 32-8). The gross specimen can exhibit multiple polyp-like structures or can be a solitary growth with a nodular, cystic, or pedunculated appearance (Hilgers, 1970). Although this distinctive appearance may guide diagnosis, the classic histologic finding of this tumor is the rhabdomyoblast (Fig. 32-9).

Malignant embryonal rhabdomyoblasts lie within a fibromyxoid stroma beneath the vaginal epithelium and cluster around blood vessels. **B.** Embryonal rhabdomyosarcoma, botryoid type (× 40). Undifferentiated round and spindled cells, some with brightly eosinophilic granular cytoplasm, are suggestive of rhabdomyoblastic differentiation. (*Courtesy of Dr. Kelley Carrick.*)

Embryonal rhabdomyosarcomas have a poor prognosis, but sarcoma botryoides is the easiest to treat and has the best chance of cure. It may be that its superficial location allows earlier detection (Copeland, 1985a).

As the result of work by the Intergroup Rhabdomyosarcoma Study (IRS) group, treatment of sarcoma botryoides has undergone dramatic revision. Before 1972, vaginal sarcoma botryoides was treated with pelvic exenteration (Hilgers, 1975). Since that time, four sequential prospective clinical trials to optimize the treatment and survival of childhood rhabdomyosarcoma have been completed. Within this series of four trials, each phase gradually shifted disease management away from radical surgery and toward primary chemotherapy followed by conservative surgery to excise residual tumor (Andrassy, 1995, 1999; Hays, 1981, 1985). In the last trial (IRS-IV), patients underwent primary chemotherapy. All but one patient, who died of chemotherapy-related toxicity, are alive without evidence of disease (Andrassy, 1999). The authors concluded that primary chemotherapy without surgery is adequate for most patients.

YOLK SAC TUMOR (ENDODERMAL SINUS TUMOR)

This type of adenocarcinoma is a germ cell tumor (see Chap. 36, Yolk Sac Tumors). Although most often developing in the gonads, yolk sac tumors rarely may arise in the vagina and usually in children aged 2 years or younger (Young, 1984). The clinical presentation is similar to that of sarcoma botryoides, and the most common symptom is bloody vaginal discharge. Grossly, the tumor differs from sarcoma botryoides, and a yolk sac tumor appears polypoid or sessile and often ulcerated (Young, 1984). On microscopic examination, these tumors most commonly have a reticular pattern. A classic finding, though not always present, is the Schiller-Duval body. This is a papilla with a single central vessel (Fig. 32-10).

FIGURE 32-10

The Schiller-Duval body is a glomerulus-like structure with a central blood vessel surrounded by embryonal cells. (*Courtesy of humpath.com.*)

Serum alpha-fetoprotein (AFP) is a useful tumor marker, and a determination should be ordered preoperatively if a yolk sac tumor is suspected. It can be used to monitor response to treatment and to detect disease recurrence before it becomes evident clinically (Copeland, 1985b).

Earlier studies demonstrated success with the chemotherapy regimen vincristine, adriamycin, and cyclophosphamide (VAC) for the treatment of yolk sac tumors (Copeland, 1985b; Young, 1984). More recently, the combination of bleomycin, etoposide, and cisplatin (BEP) has been used with excellent results (Arora, 2002; Handel, 2002; Terenziani, 2007). Neoadjuvant chemotherapy has been used to shrink the tumor and minimize or obviate surgical resection. Yolk sac tumors are responsive to radiation. However, radiotherapy should be used with caution in this age group given the severe side effects, such as loss of reproductive and sexual function, femoral head necrosis, and abnormal pelvic bone growth (Aartsen, 1993; Arora, 2002).

LEIOMYOSARCOMA

Leiomyosarcoma is the most common type of vaginal sarcoma in adults. However, it is estimated to comprise no more than 1 percent of vaginal malignancies, and only 138 cases have been described in the literature to date (Creasman, 1998).

Because of the small number of these tumors, their epidemiology has not been widely studied, and few risk factors have been identified. However, patients previously treated with pelvic radiotherapy for cervical cancer appear to be at risk.

Affected women most often complain of an asymptomatic vaginal mass. However, vaginal, rectal, or bladder pain; bleeding or discharge from the vagina or rectum; dyspareunia; or difficult micturition also may be noted. Any wall of the vagina may be affected, but most tumors develop posteriorly (Ahram, 2006). Microscopically, tumors resemble uterine leiomyosarcoma (see Fig. 34-1). Tumors spread by local invasion and hematogenous dissemination (Zaino, 2002).

Surgical resection with negative margins is the preferred primary treatment. The benefit of adjuvant radiation is unclear owing to a lack of controlled trials, however, some clinicians recommend adjuvant radiation for those with high-grade tumor or local recurrence (Curtin, 1995).

CARCINOSARCOMA (MALIGNANT MIXED MÃ¼LLERIAN TUMOR)

Carcinosarcoma contains both malignant epithelial (carcinomatous) and stromal (sarcomatous) elements. Although most commonly developing in the uterus, it can arise from other sites such as the ovaries or peritoneum. Rarely found in the vagina, these highly aggressive tumors have been described in only eight cases in the literature (Neesham, 1998; Shibata, 2003). Of these eight women, four had received prior pelvic radiation.

Given the rarity of this tumor and the lack of controlled trials, optimal treatment is unknown. Most patients have been treated with surgical resection alone, whereas others have received primary radiotherapy or combined surgery and adjuvant radiation. The 5-year survival rate is reported to be only 17 percent (Peters, 1985a).

MELANOMA

Primary malignant melanoma in the vagina is rare, accounting for less than 3 percent of all vaginal cancers. In women, 1.6 percent of melanomas are genital. The most common site is the vulva (70 percent), followed by the vagina (21 percent) and the cervix (9 percent) (see Chap. 31, Melanoma) (Miner, 2004). Using data from the U.S. National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database, Weinstock (1994) estimated that the incidence of vaginal melanoma is 0.26 per 10,000 women per year. Both U.S. and Swedish studies have shown the mean age at diagnosis to be 66 years (Ragnarsson-Olding, 1993; Reid, 1989).

The most common presenting symptoms include vaginal bleeding, vaginal mass, and vaginal discharge (Gupta, 2002; Reid, 1989). Vaginal melanoma is often detected late, and this may be largely responsible for poor treatment outcomes.

Cutaneous melanomas at other body sites are staged by a variety of microstaging systems, including the Chung, the Clark, and the Breslow systems, which use staging criteria such depth of invasion, tumor size, and tumor thickness. However, Clark levels are not applicable to vaginal melanoma because the typical skin landmarks used are not present. Therefore, staging is based on tumor thickness, as described by Breslow or Chung.

With a reported 5-year survival rate ranging from 10 to 20 percent, the prognosis is among the worst of vaginal malignancies (Beller, 2003; Ragnarsson-Olding, 1993; Signorelli, 2005; Weinstock, 1994). Although survival rates are significantly better for those with vaginal lesions measuring less than 3 cm, FIGO staging of vaginal melanomas does not accurately predict survival (Reid, 1989).

An effective treatment for vaginal melanoma has not yet been identified. Both wide local excision and radical surgery have been used, as well as radiotherapy and chemotherapy. Although melanomas generally are thought to be radioresistant, in one series, radiation therapy was found to provide local tumor control in women who had surgically unresectable disease (Miner, 2003).

ENDOMETRIAL CANCER: INTRODUCTION

In the United States, endometrial cancer is the most common gynecologic malignancy. Worldwide each year, 142,000 women are diagnosed, and 42,000 women die from this disease (Amant, 2005). Risk factors include obesity and advancing age. As both of these become more prevalent, the incidence of endometrial cancer likely will similarly increase. Fortunately, patients typically seek medical attention early due to vaginal bleeding, and endometrial biopsy leads quickly to diagnosis. The primary treatment is hysterectomy with bilateral salpingo-oophorectomy (BSO) and lymphadenectomy for most women. Three quarters of patients will have stage I disease that is curable by surgery alone. Patients with more advanced disease typically require postoperative combination chemotherapy, radiotherapy, or both.

EPIDEMIOLOGY AND RISK FACTORS

One in 38 American women (2.6 percent) will develop endometrial cancer during their lifetime. In the United States, 39,080 new cases are estimated to develop in 2007, but only 7,400 deaths are expected. Most patients are diagnosed early and are cured subsequently. As a result, endometrial cancer is the fourth leading cancer in incidence but only the eighth leading cause of cancer deaths among women (Jemal, 2007). The average age at diagnosis is the early 60s (Creasman, 1998; Farley, 2000; Madison, 2004).

Numerous risk factors for developing endometrial cancer have been described (Table 33-1). In general, most risk factors are associated with direct or indirect creation of an excessive estrogen environment.

Table 33-1 Risk Factors for Endometrial Cancer

Factors Influencing Risk	Estimated Relative Risk[a]
Obesity	2â€“5
Polycystic ovarian syndrome	>5
Long-term use of high-dose menopausal estrogens	10â€“20
Early age of menarche	1.5â€“2
Late age of natural menopause	2â€“3
History of infertility	2â€“3
Nulliparity	3
Menstrual irregularities	1.5
Residency in North America or northern Europe	3â€“18
Higher level of education or income	1.5â€“2
White race	2

Older age	2â€"3
High cumulative doses of tamoxifen	3â€"7
History of diabetes, hypertension, or gallbladder disease	1.3â€"3
Long-term use of high-dose combination oral contraceptives	0.3â€"0.5
Cigarette smoking	0.5

[a] Relative risks depend on the study and referent group employed.

From Brinton, 2004, with permission.

Of these, *obesity* is the most common cause of endogenous overproduction of estrogen. Excessive adipose tissue increases peripheral aromatization of androstenedione to estrone. In premenopausal women, elevated estrone levels trigger abnormal feedback in the hypothalamic-pituitary-ovarian axis. The clinical result is oligo- or anovulation. In the absence of ovulation, the endometrium is exposed to virtually continuous estrogen stimulation without subsequent progestational effect and menstrual withdrawal bleeding.

Unopposed estrogen therapy is the next most important potential inciting factor. Fortunately, the malignant potential of continuous or sequentially administered estrogen was recognized more than three decades ago (Smith, 1975). Currently, it is rare to encounter a woman with a uterus who has been on unopposed estrogen for years. Instead, combined estrogen plus progestin hormonal therapy is prescribed routinely for postmenopausal women with a uterus to reduce their risk of endometrial cancer (Strom, 2006). There remain questions about how effective this combination strategy is at preventing endometrial cancer, but certainly it is superior to unopposed estrogen (Lacey, 2005).

Menstrual and reproductive factors are commonly associated with endometrial cancer whenever anovulation is present or the duration of uninterrupted menstrual cycles is prolonged. For example, early age of menarche and late age of menopause are both associated with increased risk (Wernli, 2006). Classically, women with polycystic ovarian syndrome are anovulatory and thus have an increased risk of developing endometrial cancer (Pillay, 2006).

Environment may predispose to endometrial cancer in several ways. Women in Western and developed societies have a much higher incidence (Parkin, 2005). Obvious confounding variables within these populations, such as obesity and low parity, account for much of this effect. However, a possible etiologic role for nutritionâ€"especially a high dietary content of animal fatâ€"is another explanation (Goodman, 1997). Immigrant populations tend to assume the risks of native populations within one or two generations, highlighting the importance of environmental factors (Liao, 2003).

Older age is another risk factor for developing endometrial cancer, with a peak incidence among women in their 70s. Overall, about 80 percent of diagnoses occur in postmenopausal women older than 55 years (Schottenfeld, 1995). Fewer than 5 percent of endometrial cancers develop in patients younger than 40 years.

Family history is also linked to endometrial cancer. This cancer is the most common extracolonic manifestation in hereditary nonpolyposis colorectal cancer (HNPCC), also known as *Lynch syndrome* (Hemminki, 2005). This autosomal dominant syndrome results primarily from germline mutations in the mismatch repair genes *MLH1* and *MSH2* . Mutation carriers have a risk of developing endometrial cancer that ranges from 40 to 60 percent. Among women, the endometrial cancer risk actually exceeds that for colorectal cancer (Aarnio, 1999; Dunlop, 1997). However, fewer than 5 percent of endometrial cancers are attributable to HNPCC (Hampel, 2006). In general, most familial cases develop in premenopausal women (Gruber, 1996).

BRCA1 and *BRCA2* mutation carriers also have a slightly elevated risk, but only because of frequent tamoxifen treatment of previous breast cancers (Beiner, 2007). In general, these mutations mainly predispose women to breast and ovarian cancerâ€"not endometrial cancer.

Tamoxifen is used in the treatment of breast cancer (see Chap. 12, Hormonal Therapy and Targeted Therapies). It causes a two- to

threefold higher risk of developing endometrial cancer by having a modest "unopposed" estrogenic effect on the endometrium. The level of risk also increases linearly with the duration of therapy and the cumulative dose (van Leeuwen, 1994).

Most data suggest that endometrial cancers that develop in patients receiving tamoxifen exhibit the same stage, grade, and prognosis distribution as those in nonusers (Fisher, 1994). The increased risk of endometrial cancer occurs almost exclusively in postmenopausal women (Fisher, 1998). Premenopausal women treated with tamoxifen have no known increased risk of uterine cancer and do not require any additional monitoring beyond routine gynecologic care (American College of Obstetricians and Gynecologists, 2006).

Coexisting medical conditions such as diabetes mellitus, hypertension, and gallbladder disease are commonly associated with endometrial cancer (Morimoto, 2006; Soliman, 2005). In general, these are frequent sequelae of obesity and an environment of chronic excess estrogen.

Oral contraceptive use for a period of at least one year confers as much as a 30- to 50-percent reduced risk of endometrial cancer, and risk reduction extends for 10 to 20 years (Stanford, 1993). In essence, the progestin component has a chemopreventive biologic effect on the endometrium. The potency of the progestin in most oral contraceptives is adequate, but higher progestin potency may be more protective among obese women (Maxwell, 2006). Progesterone intrauterine devices (IUDs) also confer long-term protection against endometrial cancer (Tao, 2006).

Smokers have a lower risk of developing endometrial cancer. The biologic mechanism is multifactorial but in part involves reduced levels of circulating estrogens through weight reduction, an earlier age at menopause, and altered hormonal metabolism. Both current smoking and past smoking have a long-lasting influence (Viswanathan, 2005).

ENDOMETRIAL HYPERPLASIA

Most endometrial cancers arise following progression of histologically distinguishable hyperplastic lesions. In fact, endometrial hyperplasia is the only known direct precursor of invasive disease. The major criterion for establishing the diagnosis of hyperplasia is thickening of the endometrium due to an increase in the number and size of irregularly proliferating glands (Kurman, 1994). In the absence of thickening, lesions are best designated as *disordered proliferative endometrium* or *focal glandular crowding.* Endometrial hyperplasia represents a continuum of histopathologic findings that are difficult to differentiate by standard characteristics. These lesions range from anovulatory endometrium to monoclonal precancers.

Classification

WORLD HEALTH ORGANIZATION

The classification system used by the World Health Organization (WHO) and the International Society of Gynecological Pathologists designates four different types with varying malignant potential (Table 33-2) (Kurman, 1985). Hyperplasias are classified as *simple* or *complex* based on the absence or presence of architectural abnormalities such as glandular complexity and crowding (Figs. 33-1 and 33-2). Most important, hyperplasias are further designated as *atypical* if they demonstrate cytologic (i.e., nuclear) atypia. Only atypical endometrial hyperplasias are clearly associated with the subsequent development of adenocarcinoma. Simple atypical hyperplasia is a relatively uncommon diagnosis. In general, most atypical hyperplasias have a complex architecture (Figs. 33-3 and 33-4).

Table 33-2 World Health Organization Classification of Endometrial Hyperplasia

Types	Progressing to Cancer(%)
Simple hyperplasia	1
Complex hyperplasia	3
Simple atypical hyperplasia	8
Complex atypical hyperplasia	29

Complex atypical hyperplasia. *(Courtesy of Dr. Raheela Ashfaq.)*

Although endometrial hyperplasias are formally classified into these four different groups, they tend to be morphologically heterogeneous both within and between individual patients. This histologic diversity explains why only a small number of conserved features are useful as diagnostic criteria. As a result, reproducible scoring of cytologic atypia is often challenging, particularly with a small amount of tissue from a biopsy sample.

ENDOMETRIAL INTRAEPITHELIAL NEOPLASIA

Recently, the term *endometrial intraepithelial neoplasia* (EIN) has been introduced to more accurately distinguish the two very different clinical categories of hyperplasia: (1) normal polyclonal endometria diffusely responding to an abnormal hormonal environment, and (2) intrinsically proliferative monoclonal lesions that arise focally and confer an elevated risk of adenocarcinoma (Mutter, 2000). This nomenclature emphasizes the malignant potential of endometrial precancers, in keeping with similar precedents in the cervix, vagina, and vulva.

Using this system, nonatypical anovulatory or prolonged estrogen-exposed endometria generally are designated as *endometrial hyperplasias.* In contrast, *endometrial intraepithelial neoplasia* is used to describe all endometria delineated as premalignant by a combination of three morphometric features. These features reflect glandular volume, architectural complexity, and cytologic abnormality. The EIN classification system is a more accurate and reproducible way of predicting progression to cancer but has not been implemented universally (Baak, 2005; Hecht, 2005).

Clinical Features

The risk factors for developing endometrial hyperplasia generally mirror those for invasive carcinoma (Anastasiadis, 2000; Ricci, 2002). Two thirds of women present with postmenopausal bleeding (Horn, 2004). However, almost any type of abnormal uterine

bleeding should prompt diagnostic evaluation (see Chap 8, Diagnosis).

Transvaginal sonography of endometrial thickness is a feasible method for predicting endometrial hyperplasia. In postmenopausal women with endometrial measurements of 5 mm or less, sonographic pathologic studies have demonstrated that bleeding can be attributed to endometrial atrophy (see Chap. 2, Endometrium). Those with a thicker endometrium warrant biopsy. Alternatively, Pipelle (CooperSurgical, Trumbull, CT) office biopsy or outpatient dilatation and curettage (D&C) may be selected initially (Merisio, 2005). Grossly, hyperplastic endometrium is not distinctive, and thus direct visual identification using hysteroscopy is inaccurate (Garuti, 2005).

Occasionally, an adnexal mass may be palpable on examination. Although this most likely is a benign ovarian cyst, any solid features noted during transvaginal sonography should raise the possibility of a coexisting ovarian granulosa cell tumor. These tumors produce an excessive estrogenic environment that results in up to a 30-percent risk of endometrial hyperplasia or, less commonly, carcinoma (see Chap. 36, Granulosa Cell Tumors) (Ayhan, 1994).

Treatment

Management of women with endometrial hyperplasia depends mainly on the patient's age and the presence or absence of cytologic atypia. However, nonsurgical therapy is inherently risky due to the inconsistency of diagnosis and uncertainty in predicting the natural history of individual lesions. In addition, there is no way to anticipate which types will involute with progestin therapy. However, as long as an endometrial sample is representative and a provider has no reason to suspect a coexisting invasive carcinoma, the decision to treat endometrial hyperplasia through hormonal or surgical means relies on clinical judgment.

NONATYPICAL ENDOMETRIAL HYPERPLASIA

Premenopausal Women

Premenopausal women with nonatypical endometrial hyperplasia typically require a 3- to 6-month course of low-dose progestin therapy. Cyclic medroxyprogesterone acetate (MPA) (Provera, Pfizer, New York, NY) given orally for 12 to 14 days each month at a dose of 10 to 20 mg daily is commonly used. Another frequently used option is to initiate a combination oral contraceptive pill. Progesterone-containing IUDs are also effective (Wildemeersch, 2003). In some patients, hysteroscopic endometrial ablation can be curative, but posttreatment surveillance is more difficult, and subsequent hysterectomy rates are high (Jarvela, 2005). Although lesions may regress spontaneously without therapy, progestins generally are used to address the underlying etiology, i.e., chronic anovulation and excess estrogen (Terakawa, 1997). If no residual hyperplastic endometrium is found during surveillance biopsy, then patients should be continued on progestins and be monitored until menopause. An additional endometrial biopsy is required for new bleeding.

In general, biopsies should be avoided when a patient is taking progestins because this hormone confounds the pathologic diagnosis through modification of endometrial morphology. Endometrial shedding during a withdrawal bleed is also an integral component of medication-induced ablation and should be completed before assessing persistence. Waiting 2 to 6 weeks after hormone withdrawal before biopsy solves these problems.

Postmenopausal Women

Postmenopausal women with nonatypical endometrial hyperplasia also may be treated with low-dose cyclic MPA or a continuous 2.5 mg/day regimen. However, it is particularly important in older women to be confident that an adequate sample has been obtained to exclude cytologic atypia. A D&C may be indicated in some circumstances. For instance, occasionally, tissue volume with Pipelle sampling is scant, or bleeding symptoms are more prominent than expected.

In practice, postmenopausal patients with simple hyperplasia often are followed without therapy. Complex hyperplasia without atypia usually is treated with progestins. Office endometrial biopsy is performed annually to surveil these women.

Response of Nonatypical Endometrial Hyperplasia to Progestins

The overall clinical and pathologic regression rates of progestin therapy exceed 90 percent for nonatypical endometrial hyperplasia (Rattanachaiyanont, 2005). Patients with persistent disease on repeated biopsy should be switched to a higher-dose regimen such as MPA 40 to 100 mg orally daily or megestrol acetate (Megace, Bristol-Myers Squibb, New York, NY), 160 mg daily. Again, the

clinician must confirm that hormonal ablation has occurred by resampling the endometrium after a suitable therapeutic interval. Hysterectomy also should be reconsidered for lesions that are refractory to medical management.

ATYPICAL ENDOMETRIAL HYPERPLASIA

Hysterectomy is the best treatment for women at any age with atypical endometrial hyperplasia because the risk of concurrent subclinical invasive disease is high (Horn, 2004). Premenopausal women who strongly wish to preserve fertility are the main exception. High-dose progestin therapy may be most appropriate for highly motivated patients (Randall, 1997). Poor surgical candidates also may warrant an attempt at hormonal ablation with progestins. Resolution of the hyperplasia must be confirmed by serial endometrial biopsies every 3 months until response is documented. Otherwise, hysterectomy should be recommended (Orr, 2005). Following hyperplasia resolution, surveillance should continue long term due to the potential for eventual progression to carcinoma (Rubatt, 2005).

The Gynecologic Oncology Group (GOG) performed a prospective cohort study of 289 patients who had a diagnosis of atypical endometrial hyperplasia in the community. Participants underwent hysterectomy within 3 months of their biopsy, and 43 percent were found to have a concurrent endometrial carcinoma (Trimble, 2006). Results demonstrate the futility of trying to make an accurate diagnosis before hysterectomy and the potential risks of conservative hormonal treatment.

Generalists in obstetrics and gynecology who perform hysterectomy for atypical endometrial hyperplasia should be especially wary of the possibility of invasive disease and the need for surgical staging. If a gynecologic oncologist is not available, then some reports have suggested that hysteroscopic visualization may be able to identify a coexisting infiltrating carcinoma and thereby aid appropriate referral (Garuti, 2006). At a minimum, peritoneal washings should be obtained prior to performing a hysterectomy. In addition, the uterus should be opened and examined in the operating room. Any suspicion for invasive disease is an appropriate indication for intraoperative consultation with a gynecologic oncologist.

ENDOMETRIAL CANCER

Pathogenesis

Endometrial cancer is a biologically and histologically diverse group of neoplasms characterized by a dualistic model of pathogenesis. Type I endometrioid adenocarcinomas comprise 75 percent of all cases. They are estrogen dependent, low grade, and derived from atypical endometrial hyperplasia. In contrast, type II cancers usually have serous or clear cell histology, no precursor lesion, and a more aggressive clinical course (Table 33-3). The morphologic and clinical differences are paralleled by genetic distinctions in that type I and II tumors carry mutations of independent sets of genes (Hecht, 2006).

Table 33-3 Type I and II Endometrial Carcinoma: Distinguishing Features

Feature	Type I	Type II
Unopposed estrogen	Present	Absent
Menopausal status	Pre- and perimenopausal	Postmenopausal
Hyperplasia	Present	Absent
Race	White	Black
Grade	Low	High
Myometrial invasion	Minimal	Deep
Specific subtypes	Endometrioid	Serous, clear cell
Behavior	Stable	Aggressive

From Kurman, 1994, with permission.

The two pathways of endometrial cancer pathogenesis obviously have significant overlap and result in a spectrum of histologic features. However, this dualistic view has therapeutic ramifications for novel treatment strategies that target high-risk disease (Cerezo, 2006).

Prevention

SCREENING

There is currently no role for routine screening of endometrial cancer for women at average or increased risk (see Table 33-1). Instead, at the onset of menopause, women should be informed about the risks and symptoms of endometrial cancer. They should be strongly encouraged to report any unexpected bleeding or spotting to their health care provider (American College of Obstetricians and Gynecologist, 2006; Smith, 2003).

However, annual screening by endometrial sampling should begin at age 35 years in women at high risk for endometrial cancer due to HNPCC (Burke, 1997; Smith, 2003). Potential mutation carriers of this syndrome may be identified if they have first- or second-degree family members diagnosed with more than one endometrial, colon, or ovarian cancer. Referral for genetic counseling can further clarify the risk to predict which patients may benefit from specific germline testing (Balmana, 2006; Chen, 2006). Since endometrial cancer is the most common "sentinel cancer," obstetrician-gynecologists play a pivotal role in identification of women with HNPCC (Lu, 2005).

PROPHYLACTIC SURGERY

Since women with the HNPCC have such a high lifetime risk of developing endometrial cancer (40 to 60 percent), prophylactic hysterectomy is another option. In a cohort of 315 HNPCC mutation carriers, Schmeler and associates (2006) confirmed the benefit of this approach by reporting a 100-percent risk reduction. In general, BSO also should be performed because of the 10- to 12-percent lifetime risk of ovarian cancer in these women.

Diagnosis

SIGNS AND SYMPTOMS

Early diagnosis of endometrial cancer is almost entirely dependent on the prompt recognition and evaluation of irregular vaginal bleeding. In premenopausal women, a clinician must maintain a high index of suspicion for a history of prolonged, heavy menstruation or intermenstrual spotting because many other benign disorders give rise to similar symptoms (see Chap. 8, Incidence). Postmenopausal bleeding is particularly worrisome, leading to a 5- to 10-percent likelihood of diagnosing endometrial carcinoma (Gredmark, 1995; Iatrakis, 1997). Abnormal vaginal discharge may be another symptom in older women.

Unfortunately, some patients do not seek medical attention despite months or years of heavy, irregular bleeding. In more advanced disease, pelvic pressure and pain may reflect uterine enlargement or extrauterine tumor spread. Patients with serous or clear cell tumors often present with signs and symptoms suggestive of advanced epithelial ovarian cancer (see Chap. 35, Epithelial Ovarian Cancer).

PAPANICOLAOU TEST

Historically, the Pap smear has not been a sensitive tool to diagnose endometrial cancer, and 50 percent of women with endometrial cancer will have normal findings (Gu, 2001). Liquid-based cytology appears to increase the detection of glandular abnormalities but not enough to change clinical practice (Guidos, 2000; Schorge, 2002).

Benign endometrial cells are recorded occasionally on a routine Pap smear in women 40 years and older. In premenopausal women, this is often a finding of limited importance, especially if the smear is obtained following menses. However, postmenopausal women with such findings have nearly a 3- to 5-percent risk of endometrial cancer (Simsir, 2005). In those using hormone-replacement therapy, the prevalence of benign endometrial cells on smears is increased, and the risk of malignancy is less (1 to 2 percent) (Mount, 2002). Although endometrial biopsy should be considered in asymptomatic postmenopausal women if this finding is reported, most patients ultimately diagnosed with hyperplasia or cancer have concomitant abnormal bleeding

(Ashfaq, 2001).

ENDOMETRIAL SAMPLING

Office Pipelle biopsy is always preferred for the initial evaluation of women with bleeding suspicious for malignancy (Feldman, 1993). However, if sampling techniques fail to provide sufficient diagnostic information, or if abnormal bleeding persists, D&C may be required to clarify the diagnosis (Gordon, 1999).

Outpatient hysteroscopy has proved less helpful in diagnosing hyperplasia (Ben Yehuda, 1998). Moreover, diagnostic hysteroscopy has been associated with an increased incidence of positive peritoneal cytology during subsequent staging surgery (Obermair, 2000; Zerbe, 2000). Although this may not worsen an individual patient's prognosis, it does increase the initial cancer stage. As a result, physicians should be wary about performing fluid hysteroscopy routinely if a malignancy is suspected.

LABORATORY TESTING

The only clinically useful tumor marker in the management of endometrial cancer is measurement of a serum CA125 level. Preoperatively, an elevated titer indicates the possibility of more advanced disease (Powell, 2005). In practice, it is most useful in patients with advanced disease or serous subtypes to assist in monitoring response to therapy or during posttreatment surveillance. However, even in this setting, it has limited utility in the absence of other clinical findings (Price, 1998).

IMAGING STUDIES

In general, for women with a well-differentiated type I endometrioid tumor, chest radiograph is the only required preoperative imaging study. All other preoperative testing is directed toward general surgical preparation.

Computed tomographic (CT) scanning or magnetic resonance (MR) imaging usually is not necessary (Orr, 2005). However, MR imaging occasionally can help to distinguish an endometrial cancer with cervical extension from a primary endocervical adenocarcinoma (Nagar, 2006). Moreover, women with serous features or other high-risk histology on preoperative biopsy and those with physical examination findings suggesting advanced disease are most appropriate for abdominal pelvic CT scanning (Fig. 33-5). In these cases, advance knowledge of intra-abdominal disease may be helpful in guiding treatment.

Role of the Generalist

Although most endometrial cancers are cured by hysterectomy and BSO, primary management by gynecologic oncologists results in an efficient use of health care resources and minimizes potential morbidity (MacDonald, 2005; Roland, 2004). Therefore, preoperative consultation generally is advisable for any patient with endometrial cancer who is being prepared for surgery by a generalist in obstetrics and gynecology. Young or perimenopausal women with grade 1 endometrioid adenocarcinoma in a background of atypical endometrial hyperplasia are possible exceptions. However, the old axiom of a nodal dissection not being required for a grade 1 tumor no longer applies because many women will have more advanced disease than predicted by preoperative prognostic factors. In addition, intraoperative evaluation of depth of invasion is less accurate than previously thought (Frumovitz, 2004a).

Postoperatively, a gynecologic oncologist should be consulted whenever there is evidence for cervical extension, extrauterine disease, or positive peritoneal washings. In many cases, early-stage patients treated by surgery alone will return to their primary obstetrician-gynecologist for surveillance. Consultation again is recommended if recurrent disease is diagnosed or suspected.

When an endometrial cancer is diagnosed unexpectedly after hysterectomy performed by a generalist for other indications, consultation is also recommended. Possible therapeutic options include no further therapy and surveillance only, reoperation to complete surgical staging, or radiotherapy to prevent local recurrence. In general, the survival advantages of staging must be weighed against the complications from another surgical procedure (Orr, 2005). Fortunately, the advent of laparoscopic restaging has resulted in the potential for less morbidity in selected patients (Spirtos, 2005).

Pathology

There is a broad spectrum of aggressiveness within the histopathologic types of endometrial cancer (Table 33-4). Most patients have endometrioid adenocarcinomas that behave indolently. However, some will have an unfavorable histology that portends a much more aggressive tumor. In addition, the degree of tumor differentiation is an important predictor of disease spread. Tumors that arise following pelvic radiation differ from sporadic endometrial cancers by having a preponderance of high-stage, high-grade, and high-risk histologic subtypes (Pothuri, 2003). Effectively managing women with endometrial cancer requires an understanding of these interrelated clinical features.

HISTOLOGIC GRADE

The most widely used grading system for endometrial carcinoma is the three-tiered International Federation of Gynecology and Obstetrics (FIGO) system (Table 33-5). Grade 1 lesions typically have a good prognosis. Grade 2 tumors have an intermediate prognosis. Grade 3 cancers frequently have a poor prognosis and are associated with an increased potential for myometrial invasion and nodal metastasis.

Table 33-5 Histopathologic Criteria for Assessing Grade

Grade	Definition
1	≦5% of a nonsquamous or nonmorular solid growth pattern
2	6â€"50% of a nonsquamous or nonmorular solid growth pattern
3	> 50% of a nonsquamous or nonmorular solid growth pattern

From Pecorelli, 1999, with permission.

Histologic grading primarily should be determined microscopically by the tumor's architectural growth pattern (Zaino, 1994). However, there are a few exceptions, and the optimal method for determining grade is somewhat controversial. Nuclear atypia that is inappropriately advanced relative to the architectural grade raises a grade 1 or 2 tumor by one level. For example, a grade 2 lesion based on architectural features may be increased to a grade 3 lesion if significant nuclear atypia is present. This modification was shown to have prognostic utility in a GOG study of 715 endometrioid adenocarcinomas that were reviewed (protocol 33) (Zaino, 1995). Based on the FIGO system, nuclear grading also takes precedent for all serous and clear cell adenocarcinomas (Pecorelli, 1999).

In an effort to improve the reproducibility and prognostic importance of the FIGO system, a binary architectural grading system has been proposed recently (Lax, 2000; Scholten, 2005). The simplicity of dividing tumors into low- and high-grade lesions based on the proportion of solid growth (≦50 percent or >50 percent, respectively) is attractive and appears to have value. This approach, however, has not been implemented widely in clinical practice.

HISTOLOGIC TYPE

Endometrioid Adenocarcinoma

The most common histologic type of endometrial cancer is endometrioid adenocarcinoma, accounting for more than 75 percent of cases. This tumor characteristically contains glands that resemble those of the normal endometrium (Fig. 33-6). The concomitant presence of hyperplastic endometrium typically correlates with a low-grade tumor and a lack of myometrial invasion. However, when the glandular component decreases and is replaced by solid nests and sheets of cells, the tumor is classified as a higher grade (Silverberg, 2003). In addition, an atrophic endometrium is associated more frequently with high-grade lesions that are commonly metastatic (Kurman, 1994).

In addition to the characteristic appearance described, endometrioid adenocarcinomas may display variant forms (see Table 33-4). These include endometrioid adenocarcinoma with squamous differentiation and villoglandular, secretory, and ciliated cell variants (Figs. 33-7 and 33-8). In general, the biologic behavior of these variant tumors reflects that of classic endometrial adenocarcinoma.

Villoglandular endometrial adenocarcinomas are generally low grade and have a predominant papillary pattern with thin papillae and well-defined fibrovascular cores. *(Courtesy of Dr. Raheela Ashfaq.)*

Serous Carcinoma

Accounting for about 5 to 10 percent of endometrial cancers, serous carcinoma typifies the highly aggressive type II tumors that arise from the atrophic endometrium of older women (Jordan, 2001). There is typically a complex pattern of papillary growth with cells demonstrating marked nuclear atypia (Fig. 33-9). Commonly referred to as *uterine papillary serous carcinoma* (UPSC), its histologic appearance resembles epithelial ovarian cancer, and psammoma bodies are seen in 30 percent of patients (Fig. 33-10) (Silverberg, 2003).

Uterine papillary serous carcinoma (high magnificiation). Tumor cells are arranged in papillae and usually are pleomorphic with high mitotic activity *(Courtesy of Dr. Raheela Ashfaq.)*

Grossly, the tumor is exophytic with a papillary appearance emerging from a small, atrophic uterus (Fig. 33-11). These tumors occasionally may be confined within a polyp and have no evidence for spread (Carcangiu, 1992). However, UPSC has a known propensity for myometrial and lymphatic invasion. Intraperitoneal spread, such as omental caking, which is unusual for typical endometrioid adenocarcinoma, is also common even when myometrial invasion is minimal or absent (Fig. 33-12) (Sherman, 1992). As a result, it may be impossible to distinguish UPSC from epithelial ovarian cancer during surgery. Similar to ovarian carcinoma, these tumors usually secrete CA125, and serial serum measurements are a useful marker to monitor the disease postoperatively. Uterine papillary serous carcinoma is an aggressive cell type, and women with mixed endometrial cancers containing as little as 25 percent of UPSC have the same survival as those with pure serous carcinoma (Kurman, 1994).

Clear Cell Carcinoma

Fewer than 5 percent of endometrial cancers are clear cell variants, but this is the other major type II tumor (Abeler, 1991). The microscopic appearance may be predominantly solid, cystic, tubular, or papillary. Most frequently, it consists of a mixture of two or more of these patterns (Figs. 33-13 and 33-14) (Silverberg, 2003).

FIGURE 33-13

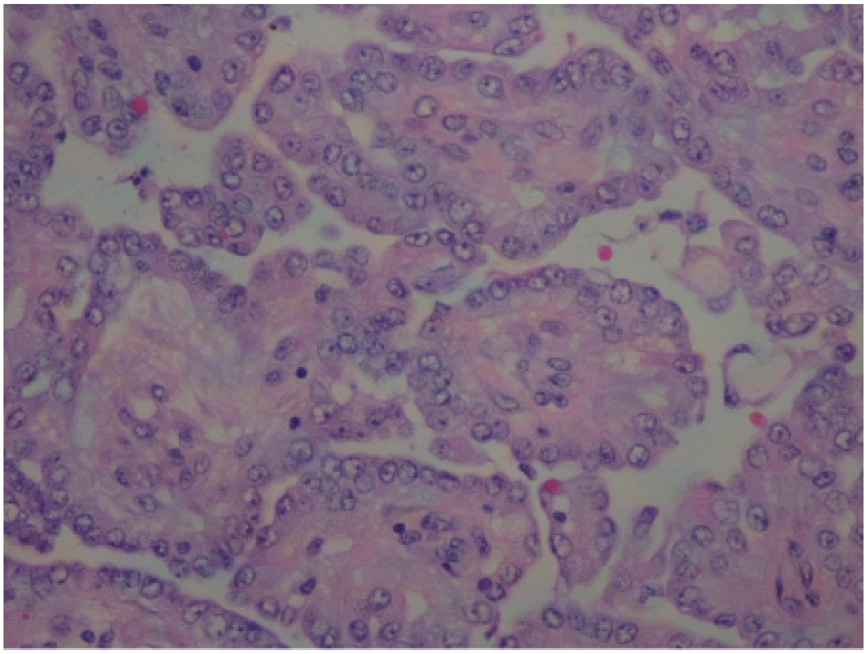
FIGURE 33-14



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Clear cell carcinoma (papillary type). *(Courtesy of Dr. Raheela Ashfaq.)*

Endometrial clear cell adenocarcinomas are similar to those arising in the ovary, vagina, and cervix. Grossly, there are no characteristic features, but like UPSC, they tend to be high-grade, deeply invasive tumors. Patients often are diagnosed with advanced disease and have a poor prognosis (Hamilton, 2006).

Mucinous Carcinoma

About 1 to 2 percent of endometrial cancers have a mucinous appearance that comprises more than half the tumor. However, many endometrioid adenocarcinomas will have a focal component (Ross, 1983). Typically, mucinous tumors have a glandular pattern with uniform columnar cells and minimal stratification (Fig. 33-15). Almost all are stage I, grade 1 lesions with a good prognosis (Melhem, 1987). Since endocervical epithelium merges with the lower uterine segment, the main diagnostic dilemma is differentiating this tumor from a primary cervical adenocarcinoma. In this situation, immuno-staining may be helpful, but preoperative MR imaging may be required to further clarify the most likely site of origin.

FIGURE 33-15

Mucinous carcinomas have endocervical-type mucin-producing cells. Note tumor cells floating in abundant mucin. *(Courtesy of Dr. Raheela Ashfaq.)*

Mixed Carcinoma

An endometrial cancer may demonstrate combinations of two or more pure types. To be classified as a mixed carcinoma, a component must comprise at least 10 percent of the tumor. Except for serous and clear cell histology, the combination of other types usually has no clinical significance. As a result, *mixed carcinoma* usually refers to an admixture of a type I (endometrioid adenocarcinoma and its variants) and type II carcinoma (Silverberg, 2003).

Undifferentiated Carcinoma

In 1 to 2 percent of endometrial cancers, there is no evidence of glandular, sarcomatous, or squamous differentiation. These undifferentiated tumors are characterized by proliferation of medium-sized, monotonous epithelial cells growing in solid sheets with no specific pattern. Overall, the prognosis is worse than in women with poorly differentiated endometrioid adenocarcinomas (Altrabulsi, 2005).

Rare Histologic Types

Fewer than 100 cases of *squamous cell carcinoma* of the endometrium have been reported. Diagnosis requires exclusion of an adenocarcinoma component and no connection with the squamous epithelium of the cervix (Varras, 2002). Typically, the prognosis is poor (Goodman, 1996). *Transitional cell carcinoma* of the endometrium is also rare, and metastatic disease from the bladder and ovary must be excluded during diagnosis (Ahluwalia, 2006).

PATTERNS OF SPREAD

Endometrial cancers have several different potential ways to spread beyond the uterus (Morrow, 1991). Type I endometrioid tumors and its variants spread most commonly, in order of frequency, by: (1) direct extension, (2) lymphatic metastasis, (3) hematogenous dissemination, and (4) intraperitoneal exfoliation. Type II serous and clear cell carcinomas have a particular propensity for extrauterine disease in a pattern that closely resembles epithelial ovarian cancer. In general, the various patterns of

spread are interrelated and often develop simultaneously.

Invasion of the endometrial stroma and exophytic expansion within the uterine cavity follow initial growth of an early cancer (Fig. 33-16). Over time, the tumor invades the myometrium and ultimately may perforate the serosa (Table 33-6). Tumors situated in the lower uterine segment tend to involve the cervix early, whereas those in the upper corpus tend to extend to the fallopian tubes or serosa. Advanced regional growth may lead to direct invasion of adjacent pelvic structures, including the bladder, large bowel, vagina, and broad ligament.

Table 33-6 Correlation of Histologic Grade and Depth of Myometrial Invasion in Stage I Patients (n = 5,095)

Myometrial Invasion	Grade		
	1	2	3
None	29%	11%	15%
≤50%	51%	59%	46%
>50%	20%	30%	39%

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of a uterine specimen with endometrioid adenocarcinoma. Tumor is seen filling the endometrial cavity and invading myometrial walls.

Lymphatic channel invasion and metastasis to the pelvic and para-aortic nodal chains can follow tumor penetration of the myometrium (Table 33-7). The lymphatic network draining the uterus is complex, and patients can have metastases to any single nodal group as well as combinations of groups (Burke, 1996). This haphazard pattern is in contrast to cervical cancer, in which

lymphatic spread usually follows a stepwise progression from pelvic to para-aortic to scalene nodal groups.

Table 33-7 Correlation of Histologic Grade and Depth of Myometrial Invasion with Risk of Nodal Metastases

	Pelvic Lymph Nodes			Para-aortic Lymph Nodes		
Myometrial Invasion	**G1**	**G2**	**G3**	**G1**	**G2**	**G3**
None	1%	7%	16%	<1%	2%	5%
≤50%	2%	6%	10%	<1%	2%	4%
>50%	11%	21%	37%	2%	6%	13%

Hematogenesis dissemination results most commonly in metastases to the lung and less commonly, to the liver, brain, bone, and other sites. Deep myometrial invasion is the strongest predictor of this pattern of spread (Mariani, 2001a).

Retrograde transtubal transport of exfoliated endometrial cancer cells is one mechanism by which malignant cells reach the peritoneal cavity. Serosal perforation of the tumor is another possible pathway. Most types of endometrial cancer cells found in the peritoneal cavity disappear within a short time and have low malignant potential (Hirai, 2001). Alternatively, in the presence of other high-risk features, such as adnexal metastases or serous histology, widespread intra-abdominal disease may result.

Treatment

SURGICAL STAGING

Women with endometrial cancer should undergo hysterectomy, BSO, and surgical staging using the FIGO system (Table 33-8). Almost three quarters of patients are stage I at diagnosis (Table 33-9). Only a few circumstances contraindicate primary surgery and include a desire to preserve fertility, massive obesity, high operative risk, and clinically unresectable disease. In general, an extrafascial ("simple") hysterectomy (see Section 41-19, Hysterectomy) is sufficient, but radical hysterectomy (see Section 43-1, Radical Abdominal Hysterectomy (Type III)) may be preferable for women with clinically obvious cervical extension of endometrial cancer (Cornelison, 1999; Mariani, 2001b). Vaginal hysterectomy with or without BSO is another option for those women who cannot undergo systematic surgical staging because of comorbidities (Orr, 2005).

Table 33-8 FIGO Surgical Staging System for Endometrial Cancer

FIGO Stage	Surgical-pathologic Findings
IA	Tumor limited to endometrium
IB	Tumor invades less than 50% of myometrium
IC	Tumor invades at least 50% of the myometrium
IIA	Tumor extends to the glandular epithelium of the endocervix
IIB	Tumor extends to the stromal connective tissue of the cervix
IIIA	Tumor involves serosa and/or adnexa (direct extension or metastasis) and/or cancer cells in ascites or peritoneal washings
IIIB	Vaginal involvement (direct extension or metastasis)
IIIC	Pelvic and/or paraaortic lymph node metastasis
IVA	Tumor invades bladder mucosa and/or bowel mucosa
IVB	Distant metastasis (i.e., inguinal nodes, omentum)

To manage a patient optimally, it is imperative to carefully review the histopathologic description of the preoperative biopsy findings. For example, papillary serous features should suggest the possibility of intraperitoneal disease in the upper abdomen that may make a vertical incision most appropriate (Orr, 2005). Traditionally, laparotomy has been the standard approach, but laparoscopic surgical staging is being used increasingly for endometrial cancer that appears clinically to be confined to the uterus.

Staging Laparotomy

Surgery begins with an adequate abdominal incision, most commonly vertical, but targeted to specific patient circumstances. On entering the peritoneal cavity, washings are obtained by pouring 50 to 100 mL of saline into the abdomen, manually circulating the fluid, and collecting it for cytologic assessment. Retrieval of ascitic fluid is a perfectly acceptable alternative, but ascites is encountered infrequently. Next, a thorough intra-abdominal and pelvic exploration is performed, and suspicious lesions are biopsied

or excised.

These preliminary procedures are followed by hysterectomy and BSO. The uterus is opened away from the operating table, and the depth of myometrial penetration may be determined by intraoperative gross examination or microscopic frozen section (Sanjuan, 2006; Vorgias, 2002). Historically, the combination of preoperative biopsy grade and intraoperative assessement of the depth of myometrial invasion were the two factors that a surgeon used to determine whether to proceed with lymph node dissection. However, recent studies have changed the paradigm.

This approach is inconsistent and frequently inadequate. It is difficult to predict with certainty the final histologic grade based on a preoperative biopsy or intraoperative frozen section (Eltabbakh, 2005). In addition, the depth of myometrial invasion determined in the operative room often is inaccurate. As a result, complete surgical staging with pelvic and para-aortic lymphadenectomy is recommended for *all* patients with endometrial cancer (see Sections 43-9, Pelvic Lymphadenectomy and 43-10, Para-Aortic Lymphadenectomy) (Frumovitz, 2004a, 2004b). At a minimum, any suspicious pelvic or para-aortic lymph nodes should be removed. Unfortunately, lymphatic mapping for a "sentinel" node does not appear to be a useful technique in endometrial cancer (see Chap. 31, Lymphadenectomy) (Frumovitz, 2007).

Higher nodal counts correlate with improved survival, most likely due to improved staging (Lutman, 2006). In addition, evidence suggests the possibility of a therapeutic benefit from multiple-site lymphadenectomy (Kilgore, 1995). Removal of grossly involved lymph nodes leads to a survival advantage (Havrilesky, 2005). Moreover, microscopic nodal disease may be resected unknowingly and prevent future relapse.

Patients with serous or clear cell features on preoperative biopsy should have extended surgical staging with an infracolic omentectomy and bilateral peritoneal biopsies of the pelvis, pericolic gutter, and diaphragm (see Section 43-12, Omentectomy) (Bristow, 2001a). As in ovarian cancer, a surgeon also should be prepared to resect any metastases (Bristow, 2000c).

Laparoscopic Staging

An alternative method of surgically staging combines a laparoscopic approach with both hysterectomy and lymphadenectomy (Ghezzi, 2006). In general, this approach is best suited to a select group of women with clinical stage I disease. However, laparoscopic pelvic and para-aortic lymph node dissection also may be an attractive option in women incompletely staged at their primary surgery (Childers, 1994).

The potential benefits of minimally invasive surgery are numerous. In general, patients have fewer blood transfusions, shorter hospital stays, lower perioperative morbidity, and better quality of life (Gil-Moreno, 2006; Zullo, 2005). Disadvantageously, surgical time typically is prolonged, exposure may be limited, limitations or bleeding may require conversion to laparotomy, and staging may be incomplete (Eitan, 2004; Spirtos, 2005). However, in selected patients, approximately 70 percent of planned cases can be completed successfully. Overall survival and recurrence rates in early reports are similar to those of a traditional abdominal approach (Magrina, 1999).

SURVEILLANCE

Most surgically treated patients simply can be followed by pelvic examination every 3 to 4 months for the first 2 years and twice yearly for an additional 3 years before returning to annual visits (Orr, 2005). Pap smears are not a mandatory part of surveillance because they identify an asymptomatic vaginal recurrence in less than 1 percent of patients and are not cost-effective (Bristow, 2006a; Cooper, 2006).

Women who have more advanced disease that requires postoperative radiation or chemotherapy or both warrant more aggressive monitoring. Serum CA125 measurements may be valuable, particularly for UPSC. Intermittent imaging using CT scanning or MR imaging also may be indicated. In general, the pattern of recurrent disease depends on the original sites of metastasis as well as the treatment received.

CHEMOTHERAPY

Paclitaxel (*T* axol), doxorubicin (*A* driamycin) and cisplatin (TAP) chemotherapy is the adjuvant treatment of choice for advanced endometrial cancer. In a randomized phase III GOG trial of 273 women (protocol 177), administration of seven courses of TAP was

superior to doxorubicin and cisplatin (AP), but toxicity was increasedâ€"particularly peripheral neuropathy (Fleming, 2004). A less toxic alternative to TAP chemotherapy is the combination of paclitaxel and carboplatin. Routinely used for the treatment of ovarian cancer, this regimen also has demonstrated efficacy in advanced-stage endometrial cancer (Hoskins, 2001; Sovak, 2006).

In practice, cytotoxic chemotherapy frequently is combined with radiotherapy in patients with advanced endometrial cancer. To reduce toxicity, directed pelvic or para-aortic radiation usually is employed rather than whole abdominal irradiation.

RADIATION

Primary Therapy

Primary radiation therapy usually is considered only in rare instances when a patient is an exceptionally poor surgical candidate. Intracavity brachytherapy such as Heyman capsules with or without external-beam pelvic radiation is the typical method (see Chap. 28, Brachytherapy). In general, the survival rate is 10 to 15 percent lower than that with surgical treatment (Chao, 1996; Fishman, 1996). These poor results suggest that a careful preoperative evaluation and appropriate consultation should be undertaken before denying any woman the benefits of hysterectomy (Orr, 2005).

Adjuvant Therapy

The use of postoperative radiation in women with stage I disease is highly controversial because of the low relapse rate and the scarcity of data from randomized trials. Most women with lower-risk surgical stage I disease may be counseled that postoperative radiation therapy can reduce the risk of recurrence in the vagina and pelvis. However, the cost and toxicity should be balanced against evidence that it does not improve survival or reduce distant metastasis (Creutzberg, 2001, 2004). In contrast, data do support treatment of women with stage IC, grade 3 endometrial adenocarcinoma with postoperative external beam pelvic radiotherapy (Aalders, 1980).

The efficacy of postoperative radiotherapy is even harder to decipher among women with surgical stage II endometrial adenocarcinoma. Most data consist of retrospective, single-institution experiences, and there is evidence to support external beam pelvic radiation, vaginal brachytherapy, both, or no further treatment (Ayhan, 2004; Calvin, 1999; Rittenberg, 2005). Currently, there is no standard approach, and most patients are treated individually based on analysis of coexisting risk factors (Feltmate, 1999).

In most women with stage III endometrial cancer, tumor-directed postoperative external beam radiation is indicated with or without chemotherapy (Schorge, 1996). Most commonly, radiation therapy is directed specifically at pelvic disease but may be extended to the para-aortic area if metastases are detected.

Few patients with stage IV disease are candidates for radiotherapy with curative intent. Infrequently, a locally confined stage IVA tumor may be an exception. With stage IVB disease, intraperitoneal metastases most often lie outside a directed radiation field. Therefore, whole abdominal irradiation generally is not preferable to chemotherapy. As a result, the role of radiotherapy generally is palliative in these women (Goff, 1994).

HORMONAL THERAPY

Primary Treatment

One of the unique characteristics of endometrial cancer is its hormone responsiveness. Rarely, progestin is used for primary treatment of women with excessively high operative risk. This may be the only feasible palliative option in a few exceptional circumstances. In other uncommon situations of clinical stage I disease and grade 1 adenocarcinoma in a poor surgical candidate, an intrauterine progestational device may be useful. In general, this strategy should be used with great caution (Dhar, 2005; Montz, 2002).

Adjuvant Hormonal Therapy

Single-agent progestins have shown activity in women with advanced disease (Lentz, 1996; Thigpen, 1999). Tamoxifen modulates the expression of the progesterone receptor and is postulated to thereby improve progestin efficacy. Clinically, high response rates have been noted with tamoxifen used adjunctively with progestin therapy (Fiorica, 2004; Whitney, 2004). In general, toxicity is very low, but this combination is used most commonly for recurrent disease.

Estrogen-Replacement Therapy

Because of the presumed role of excess estrogen in the development of endometrial cancer, there has been great concern historically that use of estrogen in women with known endometrial cancer feasibly could increase the risk of recurrence or death. However, such an effect has not been observed (Suriano, 2001). The GOG attempted to determine the effect of estrogen-replacement therapy by randomly assigning 1,236 women who had undergone surgery for stage I and II endometrial cancer to receive either estrogen or placebo. Although the study did not meet its enrollment goals, the low recurrence rate (2 percent) was promising (Barakat, 2006). Due to the potential risks and lack of proven safety, women should be counseled carefully before beginning a regimen of postoperative estrogen.

MANAGEMENT OF UTERINE PAPILLARY SEROUS CARCINOMA

This most aggressive type of endometrial carcinoma is rare, and thus, randomized trials are difficult to perform. As a result, most data are single-institution, retrospective analyses. Treatment usually is individualized but often very different from that for typical endometrioid adenocarcinoma.

When a preoperative biopsy demonstrates serous features, it is imperative to perform comprehensive surgical staging for UPSC. This includes total abdominal hysterectomy, BSO, peritoneal washings, pelvic/para-aortic nodal dissection, infracolic omentectomy, and peritoneal biopsies (Chan, 2003). Even noninvasive disease often is widely metastatic (Gehrig, 2001). Fortunately, patients tend to have a good prognosis if surgical staging confirms that disease is confined to the uterus (stage Iâ€"II) (Grice, 1998).

Occasionally, no residual UPSC is evident on the hysterectomy specimen, or the tumor minimally involves the tip of a polyp. These women with surgical stage IA can be observed safely. However, all other patients with stage I disease should be considered for adjuvant treatment. One effective strategy is to treat women with stage I disease postoperatively using paclitaxel and carboplatin for three to six cycles along with concomitant vaginal brachytherapy (Dietrich, 2005; Kelly, 2005). However, some data suggest an intrinsic radioresistance for UPSC tumors (Martin, 2005). Moreover, based on the largest reported retrospective review of surgical stage I patients, Huh and colleagues (2003) questioned the benefit of any radiation therapy.

Women with stage II UPSC are more likely to benefit from pelvic radiotherapy with or without chemotherapy. Those having stage III disease are especially prone to have recurrent disease at distant sites. Accordingly, paclitaxel and carboplatin should be considered in addition to tumor-directed radiotherapy (Bristow, 2001a; Slomovitz, 2003).

In practice, many patients will have stage IVB disease. Aggressive surgical cytoreduction is perhaps most important because one of the strongest predictors of overall survival is the amount of residual disease. Postoperatively, at least six cycles of paclitaxel and carboplatin chemotherapy are indicated (Bristow, 2001b; Moller, 2004). Alternatively, enrollment in a clinical trial such as GOG protocol 209 is another option if the woman is eligible.

FERTILITY-SPARING MANAGEMENT

Hormonal therapy without hysterectomy is an option in carefully selected young women with endometrial cancer who desperately wish to preserve their fertility. In general, this strategy should apply only to those with grade 1 adenocarcinomas (type I tumors) and with no imaging evidence of myometrial invasion. Rarely, women with grade 2 lesions may be considered candidates, although it may be advisable to further assess the disease laparoscopically (Morice, 2005). The aim of hormonal treatment is to reverse the lesion, but obviously, any type of medical management involves inherent risk of disease progression that a patient should be willing to accept (Yang, 2005).

Progestins are the most commonly used agents. Megestrol acetate, 160 mg given orally daily, has demonstrated efficacy. Alternatively, MPA may be delivered by oral or intramuscular administration at varying doses (Gotlieb, 2003a). Combinations of progestin therapy with tamoxifen and gonadotropin-releasing hormone (GnRH) agonists are used less frequently (Wang, 2002). Regardless of the hormonal agent, recurrence rates are high during long-term observation (Gotlieb, 2003b; Niwa, 2005).

Women receiving fertility-sparing conservative management must be monitored carefully by repeated endometrial biopsy or D&C every 3 months to assess treatment efficacy. If there is evidence of persistence, then a regimen may need to be changed or the dose increased. Hysterectomy and operative staging should be recommended if a lesion does not regress with hormonal therapy or

if disease progression is suspected.

Delivery of a healthy infant is a feasible expectation for women who respond to treatment and have normal histologic findings in surveillance endometrial samplings. However, assisted reproductive technologies may be required to achieve pregnancy in some of these women (see Chap. 20, Unexplained Infertility). Postpartum, patients again should be monitored regularly for recurrent endometrial adenocarcinoma (Ferrandina, 2005). In general, women should undergo hysterectomy at completion of childbearing or whenever the preservation of fertility is no longer desired.

Prognostic Factors

Many clinical and pathologic factors influence the likelihood of endometrial cancer recurrence and survival (Table 33-10). Of these, FIGO surgical stage is the most important overriding variable because it incorporates many of the most important risk factors (Table 33-11). Metastatic disease to the adnexa, pelvic/para-aortic lymph nodes, and peritoneal surfaces is reflected by FIGO stage.

Table 33-10 Poor Prognostic Variables in Endometrial Cancer
Advanced surgical stage
Older age
Histologic type: UPSC or clear cell adenocarcinoma
Advanced tumor grade
Presence of myometrial invasion
Presence of lymphovascular space invasion
Peritoneal cytology positive for cancer cells
Increased tumor size
High tumor expression levels of ER and PR

ER = estrogen receptor; PR = progesterone receptor; UPSC = uterine papillary serous carcinoma.

Table 33-11 Endometrial Cancer 5-Year Survival Rates for Each Surgical Stage (*n* = 8,100 Patients)

FIGO Stage	Survival (%)
IA	91
IB	91
IC	85
IIA	83
IIB	66
IIIA	50
IIIB	50
IIIC	57
IVA	25
IVB	20

Relapse

Patients with recurrent endometrial cancer generally require individualized treatment. In general, the site of relapse is the most important predictor of survival. Depending on the circumstances, surgery, radiation, chemotherapy, or a combination of modalities may be the best strategy. The most curable scenario is an isolated relapse at the vaginal apex in a previously unirradiated patient. These women usually are treated effectively by external beam pelvic radiotherapy. In patients who were irradiated previously, exenteration is often the only curative option (see Section 43-3, Total Pelvic Exenteration) (Barakat, 1999; Morris, 1996). Nodal recurrences or isolated pelvic disease is more likely to result in progressive disease regardless of treatment modality. However, both are often appropriate indications for external-beam radiotherapy. Salvage cytoreductive surgery also may be beneficial in selected patients (Awtrey, 2006; Bristow, 2006b).

Widely disseminated endometrial cancer or a relapse not amenable to radiation or surgery is an indication for systemic chemotherapy. Such patients should be enrolled in an experimental trial, if possible, due to the limited duration of response and the urgent need for more effective therapy. Currently, TAP is thought to be the most active cytotoxic regimen (Fleming, 2004). Paclitaxel and carboplatin is another useful combination that is being compared with TAP in GOG protocol 209. Progestin therapy with or without tamoxifen is a less toxic option that is particularly useful in selected patients (Fiorica, 2004; Whitney, 2004).

In general, effective palliation of women with incurable, recurrent endometrial cancer requires an ongoing dialogue to achieve the optimal balance between symptomatic relief and treatment toxicity.

UTERINE SARCOMA: INTRODUCTION

Malignant tumors of the uterine corpus are broadly divided into three main types: carcinomas (see Chap. 33), sarcomas, and carcinosarcomas. Although the latter two categories are rarely encountered, they tend to behave more aggressively and contribute to a disproportionate number of uterine cancer deaths. Pure sarcomas are characterized mainly by differentiation toward smooth muscle (leiomyosarcoma) or toward stromal tissue within the endometrium (endometrial stromal tumors). Carcinosarcomas are mixed tumors demonstrating both epithelial and stromal components and are also known as *malignant mixed mÃ¼llerian tumors* (MMMTs). In general, uterine sarcomas grow quickly, lymphatic or hematogenous spread occurs early, and the overall prognosis is poor. However, there are several notable exceptions among these tumors.

EPIDEMIOLOGY AND RISK FACTORS

Although sarcomas commonly have been thought to account for fewer than 5 percent of all cancers of the uterine corpus, recent studies suggest that they may comprise up to 8 percent (Brooks, 2004; Greer, 2006). In most studies, MMMT is the most prevalent subtype, accounting for about half of sarcomas, followed closely by leiomyosarcomas. Endometrial stromal tumors are uncommon and comprise less than 10 percent of all cases.

Because of the small number of these tumors, the epidemiology of uterine sarcomas has not been studied extensively. As a result, relatively few risk factors have been identified, but they include chronic excess estrogen exposure, tamoxifen use, African-American race, and prior pelvic radiation. In contrast, combination oral contraceptive pill use and smoking appear to lower the risk for these tumors.

PATHOGENESIS

Several of the identifiable risk factors for uterine sarcoma parallel those observed in endometrial carcinoma. Thus, it would seem plausible that these tumors have a similar pathogenesis. However, their morphologic diversity suggests a variety of potential pathways. For example, inactivation of the *PTEN* tumor suppressor gene is a common early event in typical type I endometrioid adenocarcinomas. These mutant clones then may undergo selective unregulated proliferation when exposed to an environment of unopposed estrogen. However, among uterine sarcomas, *PTEN* mutations are observed with any frequency in MMMTs only in endometrioid-type components (Amant, 2002). For most sarcomas, uniquely different pathways have been proposed.

Leiomyosarcomas have a monoclonal origin. Although commonly believed to arise from benign leiomyomas, for the most part, they do not. Instead, they appear to develop de novo as solitary lesions (Zhang, 2006). Supporting this theory, leiomyosarcomas have molecular pathways that have been shown to be distinct from leiomyomas or normal myometrium (Quade, 2004; Skubitz, 2003).

In endometrial stromal tumors, chromosomal aberrations are heterogeneous (Halbwedl, 2005). However, the pattern of rearrangements is clearly nonrandom, and chromosomal arms 6p and 7p are involved frequently (Micci, 2006). A loss of tumor suppressor gene function(s) is suspected, however, relatively few cases have been studied to generate a working hypothesis (Moinfar, 2004).

In general, uterine MMMTs are also monoclonal neoplasms (Wada, 1997). Therefore, both the carcinoma and sarcoma components are thought to arise from a common epithelial progenitor cell. Acquisition of any number of genetic mutations, including defects in the *p53* tumor suppressor gene and DNA mismatch repair gene, may be sufficient to trigger tumorigenesis. These early molecular defects will be shared by both components as the tumor undergoes divergent carcinomatous and sarcomatous differentiation.

Thereafter, acquired molecular defects will be discordant between the two components (Taylor, 2006). This genetic progression and subsequent diversion parallel the varying phenotypes observed in these tumors (Fujii, 2000).

DIAGNOSIS

Signs and Symptoms

As in endometrial cancer, abnormal vaginal bleeding is the most frequent presenting symptom for all histologic types of uterine sarcoma (see Chap. 8, Diagnosis) (Gonzalez-Bosquet, 1997). Moreover, women with uterine sarcoma also commonly complain of pelvic or abdominal pain. Up to a third of women will describe significant discomfort that may result from passage of clots, rapid uterine enlargement, or prolapse of a sarcomatous polyp through an effaced cervix (De Fusco, 1989). In addition, a profuse, foul-smelling discharge may be obvious. Gastrointestinal and genitourinary complaints are also common. It is worth noting that degenerating leiomyomas with necrosis can mimic all these sign and symptoms.

Due to rapid growth, a uterus may extend out of the pelvis into the middle or upper abdomen. Although uterine sarcomas tend to grow quickly, no criteria define what constitutes significant growth. Fortunately, the incidence of uterine sarcoma in such cases is extremely low (<0.5 percent), and in most instances, benign enlarging leiomyomas are found (Leibsohn, 1990; Parker, 1994).

Despite these often dramatic presentations, many women with uterine sarcoma will have few symptoms other than abnormal vaginal bleeding and a seemingly normal uterus on physical examination.

Endometrial Sampling

The sensitivity of an office endometrial biopsy or dilatation and curettage (D&C) to detect uterine sarcoma is lower than that for endometrial carcinomas. For most women with MMMT, sampling will lead to a correct diagnosis, although in many cases only the carcinomatous features are evident. The reverse is also true, and occasionally, a uterine MMMT is suspected based on endometrial biopsy findings, but no sarcomatous features are found within a hysterectomy specimen.

Symptomatic women with leiomyosarcoma receive a correct diagnosis in only 25 to 50 percent of cases. This probably is related to the origin of these neoplasms in the myometrium rather than the endometrium. Similarly, endometrial stromal nodules and sarcomas may be undetectable by pipelle biopsy, especially if the neoplasm is entirely intramural (Yang, 2002; Zaloudek, 1994).

Laboratory Testing

In selected patients, serum CA125 levels may be a somewhat useful marker of disease response. However, elevated levels usually do not directly reflect tumor burden, and as a result, the utility of the test is limited (Holcomb, 1999).

Imaging Studies

Unlike most women with endometrial carcinoma, who require only a preoperative chest radiograph, additional imaging studies often are helpful if sarcoma is diagnosed before hysterectomy. In most cases, a computed tomographic (CT) scan of the abdomen and pelvis should be performed routinely. This serves at least two purposes. First, sarcomas often violate normal soft tissue planes in the pelvis, and therefore, unresectable tumors can be identified preoperatively. Second, extrauterine metastases may be visualized. In either case, treatment may be altered based on radiographic findings.

If a diagnosis is still in question, magnetic resonance (MR) imaging is most useful for distinguishing uterine sarcoma from a benign "mimic". For example, MR imaging can assist in reliably determining whether a pedunculated mass is a submucosal leiomyoma or a prolapsing endometrial stromal tumor (Kido, 2003). As a diagnostic tool for sarcoma, sonography is far less helpful. Positron-emission tomography (PET) scanning is used most effectively for disease monitoring after completion of treatment.

Role of the Generalist

Preoperative consultation with a gynecologic oncologist is recommended for any patient with a biopsy suggesting uterine sarcoma. The potential for intra-abdominal metastases and disruption of tissue planes within the pelvis increases the technical difficulty and surgical risks. More important, the approach to staging is often subtly dissimilar to that of endometrial carcinomas. For example, because of the low rate of metastasis, it may be appropriate to sample only suspicious nodes for leiomyosarcomas instead of

performing a complete pelvic and para-aortic lymphadenectomy. In addition, it may be prudent to preserve the ovaries in a young woman with an endometrial stromal tumor because the risk of adnexal metastasis is minimal. In general, a treatment plan is best organized preoperatively, if possible.

Many uterine sarcomas are not diagnosed until surgery or several days later when a pathology report is available. As a result, unstaged cases are common, and a gynecologic oncologist should be consulted at the earliest feasible time. If the diagnosis is made postoperatively, the decision to proceed with surveillance only, reoperation, or radiotherapy varies widely depending on the type of sarcoma and other circumstances. In general, these options are less straightforward than in typical endometrial carcinomas largely because of the rarity of these tumors and the comparatively limited data supporting one strategy compared with another.

PATHOLOGY

Uterine mesenchymal tumors are classified broadly into pure and mixed tumors (Table 34-1). Pure sarcomas are virtually all homologous, differentiating into mesenchymal tissue that is normally present within the uterus, such as smooth muscle (leiomyosarcoma) or stromal tissue within the endometrium (endometrial stromal tumors). Pure heterologous sarcomas, are those composed of tissue unlike that in which it developed. These, such as uterine chondrosarcoma, are exceedingly rare.

Table 34-1 World Health Organization Histologic Classification of Mesenchymal Tumors of the Uterus
Pure mesenchymal tumors
Smooth muscle tumors
Leiomyoma, including histologic and growth-pattern variants
Leiomyosarcoma
Smooth muscle tumor of uncertain malignant potential (STUMP)
Endometrial stromal tumors
Endometrial stromal nodule

High-grade undifferentiated sarcoma
Mixed epithelial and mesenchymal tumors
Malignant mixed mullerian tumor (carcinosarcoma)
Adenosarcoma

From Hendrickson, 2003, and McCluggage, 2003, with permission.

Mixed sarcomas contain a malignant mesenchymal component admixed with an epithelial element. If the epithelial element is malignant, the tumor is termed *carcinosarcoma* or *MMMT.* If the element is benign, the term *adenosarcoma* is used. The mesenchymal component of MMMTs can be either homologous or heterologous, reflecting the potentiality of the uterine primordium.

Leiomyosarcoma

Leiomyosarcomas account for about 30 to 40 percent of uterine sarcomas and 1 to 2 percent of all uterine malignances. The average age at presentation is the early 50s, and only 15 percent develop in women younger than 40 years. Most tumors (60

percent) are stage I at the time of diagnosis. Stage II (10 percent), stage III (10 percent), and stage IV (20 percent) disease comprise the remainder (Giuntoli, 2003).

The histopathologic criteria for diagnosing leiomyosarcoma is somewhat controversial but includes the frequency of mitotic figures, the extent of nuclear atypia, and the presence of any coagulative tumor cell necrosis (Table 34-2 and Fig. 34-1). Occasionally, a leiomyosarcoma will be reported as low, intermediate, or high grade, but the overall utility of grading is controversial, and no universally accepted grading system exists. In most cases, the mitotic index exceeds 15 mitotic figures per 10 high-power fields, moderate to severe cytologic atypia is seen, and tumor cell necrosis is prominent (Hendrickson, 2003; Zaloudek, 1994).

Table 34-2 Diagnostic Criteria for Uterine Leiomyosarcoma

Coagulative tumor cell necrosis	Mitotic Index	Degree of Atypia
Present	≥10 MF/10 HPF	None
	Any	Diffuse, significant
Absent	≥10 MF/10 HPF	Diffuse, significant

MF/10 HPF = mitotic figure(s) per 10 high-power fields.

In contrast to leiomyomas, leiomyosarcomas are cellular, with nuclear atypia and increased mitoses. **C.** High-grade pleomorphic sarcomas can have bizarre nuclei and mitoses and invade the myometrium. *(Courtesy of Dr. Raheela Ashfaq.)*

SMOOTH MUSCLE TUMOR OF UNCERTAIN MALIGNANT POTENTIAL (STUMP)

Tumors that cannot be diagnosed reliably as benign or malignant based on generally applied criteria fall into this category. The diagnosis should be used sparingly and is reserved for smooth muscle neoplasms whose appearance is ambiguous (Hendrickson, 2003).

Endometrial Stromal Tumors

Significantly less common than leiomyosarcomas or uterine MMMTs, endometrial stromal tumors comprise fewer than 10 percent of all uterine sarcomas. Patients typically are diagnosed in their late 40s and early 50s, younger than women developing other uterine malignancies. Although constituting a wide morphologic spectrum, endometrial stromal tumors are composed exclusively of cells that resemble the endometrial stroma and include both benign stromal nodules and malignant stromal tumors.

Historically, there has been controversy about subdivision of these tumors. Recently, the division of endometrial stromal sarcomas into low- and high-grade categories has fallen out of favor. In its place, the designation *endometrial stromal sarcoma* is now best restricted to neoplasms that formerly were referred to as low grade. Alternatively, the term *high-grade undifferentiated sarcoma* is believed to more accurately reflect those tumors without recognizable evidence of a definite endometrial stromal phenotype. These lesions are almost invariably high grade and often resemble the mesenchymal component of a uterine MMMT (Oliva, 2000). In this revised classification, the distinctions are not determined by mitotic count but rather on features such as nuclear pleomorphism and necrosis (Evans, 1982; Hendrickson, 2003).

ENDOMETRIAL STROMAL NODULE

Representing less than a quarter of endometrial stromal tumors, these rare nodules are benign, characterized by a well-delineated margin, and composed of neoplastic cells that resemble proliferative-phase endometrial stromal cells. Grossly, the tumor is a solitary, round or oval, fleshy nodule measuring a few centimeters. Histologically, they are distinguished from endometrial stromal sarcomas by a lack of myometrial infiltration (Dionigi, 2002). These nodules are benign, and myomectomy is an appropriate option. However, because differentiation between endometrial stromal sarcoma and this benign lesion cannot be determined clinically, it is important to remove the entire nodule. Thus, for large lesions, hysterectomy may be required (Hendrickson, 2003).

ENDOMETRIAL STROMAL SARCOMA

The precise frequency of these tumors is difficult to estimate because they are excluded from some reports and included in others, and the terminology used has been inconsistent. In general, endometrial stromal sarcomas (formerly called *low grade*) are thought to be the most frequently encountered stromal tumor variant and are twice as common as high-grade undifferentiated sarcomas.

Most commonly, they extensively invade the myometrium and extend to the serosa in about half of cases. Less often, they present as a solitary, well-delineated, predominantly intramural mass that is difficult to distinguish grossly from an endometrial stromal nodule. Microscopically, endometrial stromal sarcomas resemble the stromal cells of proliferative-phase endometrium (Fig. 34-2).

FIGURE 34-2

Photomicrograph of endometrial stromal sarcoma. **A.** Endometrial stromal type cells infiltrate the myometrium. **B.** The tumor often plugs the uterine vasculature and is CD10-positive (**C**). CD10 is a immunohistochemical marker of normal endometrial stroma. Staining is found in endometrial stromal nodules and endometrial stromal sarcoma. When strong and diffuse, CD10 staining may be useful in distinguishing these tumors from histological mimics. *(Courtesy of Dr. Raheela Ashfaq.)*

Metastases are rarely detected prior to diagnosis of the primary lesion. However, permeation of the lymphatic and vascular channels is characteristic. In up to a third of cases, extrauterine extension is present, often appearing as worm-like plugs of tumor within the vessels of the broad ligament and adnexa. At operation, this may resemble intravenous leiomyomatosis or a broad ligament leiomyoma, but frozen-section analysis usually can make the distinction (see Chap. 9, Leiomyomatosis).

HIGH-GRADE UNDIFFERENTIATED SARCOMA

Compared with endometrial stromal sarcomas, these tumors tend to be larger and more polypoid, often filling the uterine cavity. Instead of an infiltrating pattern, high-grade undifferentiated sarcomas displace the myometrium more destructively, leading to prominent hemorrhage and necrosis.

Microscopically, the cells are larger and more pleomorphic. The presence of marked cellular atypia is characteristic (Fig. 34-3).

Typically, there are greater than 10 mitoses per 10 high-power fields, but frequently there are more than 20 in the most active areas. These tumors lack specific differentiation and bear no histologic resemblance to endometrial stroma (Hendrickson, 2003; Zaloudek, 1994).

Malignant Mixed MÃ¼llerian Tumor (MMMT)

Accumulating clinical and pathologic evidence suggests that MMMTs actually represent endometrial carcinomas that have undergone clonal evolution, resulting in the acquisition of sarcomatous features. In principle, these tumors are metaplastic carcinomas. Clinically, their pattern of spread more closely mirrors that of aggressive endometrial carcinomas than that of sarcomas. In addition, metastases usually show carcinomatous elements (with or without sarcomatous differentiation).

However, by convention, MMMTs are grouped with uterine sarcomas and account for about half of all these tumors. Of all uterine malignancies, about 2 to 3 percent are MMMTs. Patients are often elderly, having an average age of 65 years. Less than 5 percent are diagnosed in women younger than 50 years. Most cancers (40 percent) are stage I at the time of diagnosis. Stage II (10 percent), stage III (25 percent), and stage IV (25 percent) disease make up the remainder (Sartori, 1997; Vaidya, 2006).

Grossly, the tumor is sessile or polypoid, bulky, necrotic, and often hemorrhagic. It often fills the endometrial cavity and deeply invades the myometrium. In classic cases, a large tumor protrudes through the external cervical os and fills the vaginal vault.

Microscopically, MMMTs have an admixture of epithelial and mesenchymal differentiation. The malignant epithelial element is typically an adenocarcinoma of endometrioid type, but serous, clear cell, mucinous, squamous cell, and undifferentiated carcinomas are also common (Fig. 34-4) (see Table 33-4). Mesenchymal components can be homologous, usually resembling endometrial stromal sarcomas or fibrosarcomas. Alternatively, heterologous mesenchymal differentiation can be found in association with areas of endometrial stromal or undifferentiated sarcomas. Most commonly, rhabdomyosarcoma or chondrosarcoma comprises these cases of heterologous mesenchymal differentiation (Fig. 34-5). There is no clinical importance to designating a uterine MMMT as homologous or heterologous (McCluggage, 2003; Zaloudek, 1994).

Adenosarcoma

These rare biphasic neoplasms are characterized by a benign epithelial component and a sarcomatous mesenchymal component. They may develop in women of all ages. Grossly, adenosarcomas grow as exophytic polypoid masses that extend into the uterine cavity. Rarely, they may arise in the myometrium, presumably from adenomyosis. Microscopically, isolated glands are dispersed throughout the mesenchymal component and often are dilated or compressed into thin slits (Fig. 34-6). Typically, the mesenchymal component resembles an endometrial stromal sarcoma or fibrosarcoma and contains varying amounts of fibrous tissue and smooth muscle.

FIGURE 34-6

In general, these are considered low-grade tumors with mild atypia and relatively few mitotic figures. However, 10 percent have a more malignant behavior due to one-sided proliferation of the sarcomatous, often high-grade component. These adenosarcomas are designated as having "sarcomatous overgrowth", and patients have a poor prognosis, similar to that of MMMTs (Krivak, 2001; McCluggage, 2003).

PATTERNS OF SPREAD

Uterine sarcomas generally fall into two categories of malignant behavior. First, leiomyosarcomas, high-grade undifferentiated sarcomas, and MMMTs are consistently characterized by an aggressive growth pattern, early lymphatic or hematogenous dissemination, and rapid disease progression despite treatment. In contrast, endometrial stromal sarcomas and adenosarcomas have an indolent growth pattern with long disease-free intervals. All these tumors grow, to some degree, by direct extension.

Leiomyosarcomas have a propensity for hematogenous dissemination. For example, lung metastases are particularly common, and more than half of patients will have distant spread when diagnosed with recurrent disease. To a lesser extent, leiomyosarcomas metastasize via lymphatic channels. In a clinicopathologic Gynecologic Oncology Group (GOG) study, fewer than 5 percent of clinical stage I and II patients had nodal involvement (Major, 1993).

The opposite is true for MMMTs, in which half of patients with clinically stage I tumors will have nodal metastases. Extra-abdominal spread is less common, and most recurrences are found in the pelvis or abdomen.

STAGING

There is no specific staging system for uterine sarcomas due to their rarity. Tumors were classified initially by criteria modified from the clinical staging system for endometrial carcinoma (Table 34-3). Currently, however, most clinicians use the International Federation of Gynecology and Obstetrics (FIGO) surgical staging system for endometrial cancer to stage uterine sarcomas (see Table 33-8).

Table 34-3 FIGO Staging of Uterine Sarcomas

Stage	Description
I	Sarcoma is confined to the corpus.
II	Sarcoma has involved both the corpus and the cervix.
III	Sarcoma has extended outside the uterus but not outside the true pelvis.
IV	Sarcoma has extended outside the true pelvis or has involved the mucosa of the bladder or rectum

FIGO = International Federation of Gynecology and Obstetrics.

TREATMENT OF EARLY-STAGE DISEASE

Surgery

The highest chance of cure is achieved by complete surgical resection of a tumor that is confined to the uterus. In general, an abdominal procedure is performed because of the typical features of sarcomas, which include uterine enlargement, parametrial extension, and tumor metastasis. For the most part, these patients are not suitable candidates for laparoscopic or vaginal surgery.

The staging laparotomy described for endometrial cancer can be revised in several ways to incorporate the unique spread patterns

of uterine sarcoma (see Chap. 33, Staging Laparotomy). For instance, peritoneal washings may be obtained easily on opening the abdomen but have limited value. Exploration is particularly important to assess the abdomen for unresectable or widely metastatic disease that might indicate a need to abort the procedure. Unlike endometrial carcinomas, there is no benefit to aggressive cytoreductive surgery.

With uterine leiomyosarcoma, all patients should undergo a hysterectomy, if feasible. A modified radical or radical procedure may be required occasionally if there is parametrial infiltration. In the absence of other gross disease, fewer than 5 percent of patients will have ovarian or nodal metastases. Ovarian preservation is therefore an option for premenopausal women. In addition, lymph node dissection should be reserved for patients with clinically suspicious nodes (Leitao, 2003; Major, 1993). For STUMP, hysterectomy alone is sufficient.

Endometrial stromal tumors and adenosarcomas also are best treated by hysterectomy. Again, a more radical procedure may be required to encompass local disease. Preservation of the ovaries generally is accepted for endometrial stromal sarcomas or adenosarcomas in the absence of extrauterine disease (Li, 2005). However, bilateral salpingo-oophorectomy (BSO) is indicated for high-grade undifferentiated sarcomas (Leibsohn, 1990). As with leiomyosarcoma, sampling of suspicious nodes is sufficient because detection of subclinical nodal disease has minimal impact on clinical management. Specifically, nodal metastases typically are identified only in patients with obvious extrauterine disease and portend rapid disease progression (Goff, 1993).

For uterine MMMT, hysterectomy and BSO are mandatory. Lymph node metastases develop in 15 to 20 percent of patients with clinical stage I disease, and thus retroperitoneal nodes should be sampled as for poorly differentiated endometrial cancers (Major, 1993). Typically, disease spread is consistent histologically with the carcinomatous element of this mixed tumor. Because this component may be serous or clear cell, extended surgical staging with infracolic omentectomy and random peritoneal biopsies is also advisable.

Surveillance

In women with surgical stage I uterine sarcoma, no adjuvant treatment has been demonstrated to improve survival. However, because the recurrence rate for the clinically aggressive types is excessive, enrollment in an experimental clinical trial should be considered carefully, if available. In practice, many patients receive postoperative radiation with or without chemotherapy, although data to support these treatments are limited. The remainder is simply monitored without further treatment. Women with endometrial stromal sarcoma should not receive estrogen-replacement therapy because of exquisite hormonal sensitivity of these tumors and the potential for disease progression (Chu, 2003; Pink, 2006).

Surgically treated stage I patients should have a physical examination every 3 months for the first 2 years and then at 6- to 12-month intervals thereafter. Most recurrences will be distant, and thus Pap tests are largely irrevelant. In addition, serum CA125 levels are not usually helpful. Depending on the sarcoma type, a chest radiograph should be performed every 3 to 6 months for 2 years and then annually. In many cases, intermittent CT scanning or MR imaging also may be indicated (Greer, 2006).

Adjuvant Radiation or Chemotherapy

The role of postoperative radiotherapy for nonmetastatic disease is controversial because most available data are retrospective. Prior retrospective studies of adjuvant radiotherapy have demonstrated a reduction in pelvic recurrence for MMMTs, leiomyosarcoma, and endometrial stromal sarcoma (Callister, 2004; Hornback, 1986). However, preliminary results from a prospective trial that randomly assigned women with surgical stage I or II uterine sarcomas to receive either pelvic radiation or no further treatment were reported recently. Although a reduction in pelvic relapse for those with MMMTs was noted, there was no benefit for those with leiomyosarcomas or endometrial stromal sarcomas (Reed, 2003). Whether these results will shape future treatment awaits final maturation of these early data.

In summary, most clinicians agree that enough evidence still supports use of pelvic radiation or brachytherapy with or without chemotherapy for surgical stage I and II leiomyosarcomas, MMMTs, and high-grade undifferentiated sarcomas (Greer, 2006; Le Pechoux, 2006).

Pelvic radiation, however, does not prevent distant recurrences. Accordingly, whole abdominal radiotherapy has been investigated to treat those with stage Iâ€"IV uterine MMMT. Study results are pending, but preliminary data do not suggest a benefit for whole

abdominal radiotherapy. Similarly, chemotherapy appears to be an ineffective adjuvant for most early-stage uterine sarcomas, and there is no proven role for chemotherapy in stage I disease following complete surgical resection.

Fertility-Sparing Management

Rarely, young patients may desire and meet criteria for fertility-sparing surgery. Although conservative management following tumor resection can result in successful pregnancies in selected patients, it is risky not to perform a hysterectomy for uterine sarcoma in most patients, even if margins are thought to be negative (Lissoni, 1998). Instead, if ovaries are left in situ during surgery for clinical stage I uterine leiomyosarcomas or endometrial stromal sarcomas, then egg retrieval and assisted reproductive technologies still would be possible (see Chap. 20, Assisted Reproductive Technologies). For more advanced disease, fertility-sparing management is not a reasonable option.

TREATMENT OF ADVANCED/RECURRENT DISEASE

Patients with advanced or recurrent uterine sarcoma generally have a dismal prognosis. In some circumstances, surgical resection may be feasibleâ€"for example, exenteration for an isolated relapse of leiomyosarcoma that develops following a long disease-free interval (Wydra, 2006). Palliative radiation also may have a role depending on the site and distribution of the tumor. In general, uterine sarcomas have a propensity for relapse at distant sites, and chemotherapy is required. However, current treatment options have modest efficacy, and patients should be encouraged to enroll in experimental clinical trials.

Leiomyosarcoma

Historically, doxorubicin was considered the most active single agent (Omura, 1983). However, treatment with ifosfamide or the combination of gemcitabine and docetaxel also has lead to clinical responses (see Chap. 27, Chemotherapeutic Drugs). (Bay, 2006; Hensley, 2002; Sutton, 1992).

For late recurrences of leiomyosarcoma, surgery must be individualized. Five-year survival rates of 30 to 50 percent have been reported following pulmonary resection for lung metastases. Local and regional recurrences also may be amenable to surgical resection.

Endometrial Stromal Tumors

Surgical resection may be feasible for some patients with recurrent endometrial stromal sarcoma, but hormone therapy is known to be particularly useful. In general, these tumors are estrogen- and progesterone-receptor (ER/PR) positive (Sutton, 1986). Progestins such as megestrol acetate and medroxyprogesterone acetate are used most commonly either postoperatively for advanced-stage disease or for relapses (Reich, 2006). Using this strategy, complete responses are often possible. Aromatase inhibitors and gonadotropin-releasing hormone (GnRH) agonists also have demonstrated activity (Burke, 2004; Leunen, 2004).

High-grade undifferentiated sarcomas do not exhibit the same level of sensitivity to hormonal agents primarily because they are usually ER/PR negative. Advanced disease or recurrences of these extremely rare tumors also typically are not amenable to surgical resection, although palliative radiation may have some utility. Systemic chemotherapy is usually the only option, and ifosfamide is currently being investigated (Mansi, 1990; Sutton, 1996).

Malignant Mixed MÃ¼llerian Tumor (MMMT)

The combination of ifosfamide and paclitaxel is the current treatment of choice for advanced or recurrent uterine MMMT. In a recent phase III GOG trial randomizing 179 patients, this regimen demonstrated a superior response rate (45 versus 29 percent) and survival advantage compared with ifosfamide alone (protocol 161) (Homesley, 2007). However, in general, effective palliative chemotherapeutic options for uterine MMMT are limited.

SURVIVAL AND PROGNOSTIC FACTORS

In general, women with uterine sarcoma have a poor prognosis (Table 34-4). In a study of 141 women followed for a median of 3 years, 74 percent died of disease progression. Of prognostic factors, FIGO stage is the most important overriding variable (Livi, 2003).

Table 34-4 Overall Survival of Uterine Sarcomas (All Stages)

Type	5-Year Survival
Malignant mixed mÃ¼llerian tumor	35%
Leiomyosarcoma	25%
Endometrial stromal tumors	
Endometrial stromal sarcoma	60%
High-grade undifferentiated sarcoma	25%

Compiled from Acharya, 2005, with permission.

Tumor histology is the other main predictor of clinical outcome. Leiomyosarcomas have the worst prognosis and are followed by MMMT and high-grade undifferentiated sarcomas (Livi, 2003). Endometrial stromal sarcomas and uterine adenosarcomas without sarcomatous overgrowth are the two notable exceptions. Patients with these tumors tend to have a good prognosis with an indolent growth pattern (Pautier, 2000; Verschraegen, 1998).

EPITHELIAL OVARIAN CANCER: INTRODUCTION

In the United States, ovarian cancer accounts for more deaths than all other gynecologic malignancies combined. Worldwide each year, 204,000 women are diagnosed, and 125,000 women die from this disease (Sankaranarayanan, 2006). Of these, epithelial ovarian carcinomas comprise 90 to 95 percent of all cases, including the more indolent low-malignant-potential (borderline) tumors (Quirk, 2005). Because of the similarities of primary peritoneal carcinomas and fallopian tube cancers, they are included within this section for simplicity. In general, there is no effective screening test for ovarian cancer and few notable early symptoms. As a result, three quarters of patients have advanced disease when they are diagnosed. Aggressive debulking surgery, followed by platinum-based chemotherapy, usually results in clinical remission. However, up to 80 percent of women will develop a relapse that eventually leads to disease progression and death.

EPIDEMIOLOGY AND RISK FACTORS

One in 78 American women (1.3 percent) will develop ovarian cancer during her lifetime. Because the incidence has been declining slowly since the early 1990s, ovarian cancer has dropped to the eighth leading cause of cancer in women. In 2007, 22,430 new cases are estimated to develop in the United States. However, few patients are diagnosed early and subsequently cured. As a result, 15,280 deaths are expected, and ovarian cancer remains the fifth leading cause of cancer-related death (Jemal, 2007). Overall, the average age at diagnosis is in the early 60s.

Numerous reproductive, environmental, and genetic risk factors have been associated with the development of ovarian cancer (Table 35-1). The most important is a *family history* of breast or ovarian cancer, and approximately 5 to 10 percent of patients have an inherited genetic predisposition. For the other 90 to 95 percent with no identifiable genetic link for their ovarian cancer, most risk factors are related to a pattern of uninterrupted ovulatory cycles during the reproductive years. Repeated stimulation of the ovarian surface epithelium is hypothesized to lead to malignant transformation.

Table 35-1 Risk Factors for Developing Epithelial Ovarian Cancer
Nulliparity
Early menarche
Late menopause
White race
Increasing age
Residence in North America and northern Europe
Family history

Nulliparity is associated with long periods of repetitive ovulation, and women without children have double the risk of developing ovarian cancer (Purdie, 2003). Those with a history of infertility have an even higher risk. Although the reasons are unclear, it is more likely to be an inherent ovarian predisposition than an iatrogenic effect of ovulation-inducing drugs. For example, women

treated for infertility who achieve a live birth do not have an increased risk of ovarian cancer (Rossing, 2004). In general, risks decrease with each live birth, eventually plateauing in women delivering five times (Hinkula, 2006). One interesting theory to explain this protective effect is that pregnancy may induce shedding of premalignant ovarian cells (Rostgaard, 2003).

Early menarche and late menopause also have been associated with an increased risk of ovarian cancer. In contrast, breast feeding has a protective effect, perhaps by prolonging amenorrhea (Yen, 2003). Presumably by also preventing ovulation, long-term combination oral contraceptive use reduces the risk of ovarian cancer by 50 percent. The duration of protection lasts up to 25 years after the last use (Riman, 2002). In contrast, estrogen-replacement therapy after the menopause has an elevated risk (Lacey, 2006).

White women have the highest incidence of ovarian cancer among all racial and ethnic groups (Quirk, 2005). Compared with that of black and Hispanic women, the risk is elevated by 30 to 40 percent (Goodman, 2003). Although exact reasons are unknown, racial discrepancies in parity and rates of gynecologic surgery may account for some of the differences.

Tubal ligation and *hysterectomy* each have been associated with a substantial reduction in the risk of developing ovarian cancer (Hankinson, 1993). It has been postulated that any type of gynecologic procedure that precludes irritants from reaching the ovaries via ascension from the lower genital tract plausibly might exert a similar protective effect. For example, women who regularly use perineal talc have an elevated risk (Ness, 2000).

The overall incidence of ovarian cancer rises with *increasing age* up to the mid-70s before declining slightly among women beyond 80 years (Goodman, 2003). In general, aging allows an extended time to accumulate random genetic alterations within the ovarian surface epithelium.

Women *residing in North America, northern Europe,* or *any industrialized Western country,* for example, Israel, have a higher risk of ovarian cancer. Globally, the incidence varies greatly, but developing countries and Japan have the lowest rates. Regional dietary habits may be partly responsible (Kiani, 2006). For example, consumption of foods low in fat but high in fiber, carotene, and vitamins appears protective (Zhang, 2004).

A *family history* of ovarian cancer in a first-degree relative, that is, a mother, daughter, or sister, triples a woman's lifetime risk of developing ovarian cancer. The risks further escalate with two or more afflicted first-degree relatives. Identification of high-risk patients with family members having ovarian, breast, or colon cancer is currently the best prevention strategy (National Cancer Institute, 2007a). If a family history is comprised mainly of colon cancer, clinicians should be aware of the possibility of *hereditary nonpolyposis colorectal cancer* (HNPCC), also known as *Lynch syndrome.* Patients with this syndrome have a high lifetime risk of colon cancer (85 percent) and ovarian cancer (10 to 12 percent). Because the predominant gynecologic malignancy is endometrial cancer (40 to 60 percent lifetime risk), HNPCC is described in more detail in Chapter 33.

Hereditary Breast and Ovarian Cancer

GENETIC SCREENING

More than 90 percent of inherited ovarian cancers result from germline mutations in the *BRCA1* or *BRCA2* genes. Thus, any woman with two family members having ovarian or premenopausal (before age 50) breast cancer among their first- or second-degree relatives should be referred for genetic counseling (Frank, 1998).

Typically, a comprehensive pedigree is constructed, and risk assessment is performed. BRCAPRO is currently the only validated statistical model for assessing an individual's risk for carrying a germline deleterious mutation of the *BRCA1* and *BRCA2* genes. This model and its associated software allow accurate quantification of this risk, and its results determine whether a patient should undergo genetic testing (Euhus, 2002; James, 2006).

BRCA1 AND *BRCA2* GENES

These are two tumor suppressor genes whose protein products, BRCA1 and BRCA2, interact with recombination/DNA-repair proteins to preserve intact chromosome structure. Mutations of *BRCA1* and *BRCA2* lead to genetic instability, subjecting cells to a higher risk of malignant transformation (Fig 35-1) (Deng, 2006; Scully, 2000). The *BRCA1* gene is located on chromosome 17q21. Patients with a proven mutation have a dramatically elevated risk of developing both breast (45 to 85 percent) and ovarian (20 to

45 percent) cancer. *BRCA2* is located on chromosome 13q12 and, in general, is less likely to lead to breast (30 to 50 percent) and ovarian (10 to 20 percent) cancer (Chen, 2006; Risch, 2006). Both genes are inherited in an autosomal dominant fashion, with variable penetrance. In essence, a carrier has a 50:50 chance of passing the gene to a son or daughter, but it is uncertain whether anyone with the gene mutation actually will develop breast or ovarian cancer. As a result, manifestations of *BRCA1* and *BRCA2* mutations can appear to skip generations.

FIGURE 35-1

Diagram describing the affects of the *BRCA* mutation leading to tumor development. Cells with damaged DNA are frequently blocked at checkpoints along the cell cycle and thereby prohibited from moving to the mitotic phase. *(Modified from Scully, 2000, with permission.)*

GENETIC TESTING

The main purpose of genetic testing is to identify women with deleterious *BRCA1* and *BRCA2* mutations, to intervene with prophylactic surgery, and thereby to prevent ovarian cancer. Three distinct results are possible with this testing. The first is identifying a recognized BRCA mutation. A positive test suggests the presence of a deleterious mutation. The most common are the three "Jewish founder" mutations: 185delAG or 5382insC in *BRCA1* and 6174delT in *BRCA2* . Each of these frameshift mutations significantly alters the downstream amino acid sequence, resulting in alteration of the BRCA1 or BRCA2 tumor suppressor protein.

As suggested, founder mutations are thought to have originated from within the Ashkenazi population thousands of years ago. As a result, Ashkenazi women with a single first-degree relative having either ovarian or premenopausal breast cancer also should be referred for genetic counseling.

Although Jewish founder mutations are most common, any frameshift mutation within the *BRCA* genes may result in a deleterious

predisposition to developing breast and ovarian cancer. These "variants of uncertain clinical significance" represent a second result of BRCA testing. These mutations actually may be pathogenic (true mutations) or may be just polymorphisms (normal variants found in at least 1 percent of alleles in the general population). These unclassified variants are common, representing about a third of *BRCA1* test results and half of those for *BRCA2* . Most are missense mutations, which result in a single-amino-acid change in the protein without a frameshift. Because of their uncertain clinical relevance, it is reasonable to ignore them and base patient counseling on family history (Gomez-Garcia, 2005).

Lastly, the third and most reassuring genetic test result is negative. However, because of the large size of the *BRCA1* and *BRCA2* genes, there is a false-negative rate of about 10 percent.

PREVENTION

Ovarian Cancer Screening

In addition to genetic testing, other screening strategies for ovarian cancer have been evaluated. However, despite enormous effort, there is no proof that routine screening with serum markers, sonography, or pelvic examinations decreases mortality. Hundreds of possible markers have been identified, yet no test currently available approaches sufficient levels of accuracy (American College of Obstetricians and Gynecologists, 2002).

HIGH-RISK WOMEN

For the most part, screening strategies are directed at *BRCA1* or *BRCA2* mutation carriers, in addition to women with a strong family history of breast and ovarian cancer. Most commonly, cancer antigen 125 (CA125) measurements and/or transvaginal sonography have been tested, albeit with marginal success. However, in *BRCA1* or *BRCA2* mutation carriers who do not wish to undergo prophylactic surgery, a combination of thorough pelvic examination, transvaginal sonographic evaluation, and CA125 blood testing should be offered.

By itself, CA125 is not a useful marker for detecting ovarian cancer. However, recently, a more sensitive *r* isk of *o* varian *c* ancer *a* lgorithm (ROCA) has been developed. This algorithm is based on the slope of serial CA125 measurements drawn at regular intervals (Kruitwagen, 1996; Skates, 2003). If a ROCA score exceeds a 1 percent risk of having ovarian cancer, patients undergo transvaginal sonography to determine whether additional intervention is warranted. This strategy is currently being studied prospectively among more than 2,000 high-risk women by the Gynecologic Oncology Group (GOG, protocol 199) and the National Cancer Instituteâ€"Cancer Genetics Network.

GENERAL POPULATION

Because no sufficiently accurate early detection tests are available currently, routine screening for women at average risk is not recommended. For example, in the U.S. prospective Prostate, Lung, Colorectal, and Ovarian (PLCO) Trial of screening versus usual care, 39,115 women were randomly assigned to CA125 and transvaginal sonography screening (Buys, 2005). Of those with an initially abnormal CA125 result and/or sonogram findings, 1 percent had invasive ovarian cancer, demonstrating a relatively low predictive value of both tests. To evaluate the efficacy, cost, morbidity, compliance, and acceptability of ROCA-based CA125 screening and study-directed sonography, a randomized trial of 200,000 asymptomatic postmenopausal women at average risk is currently underway [United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS)].

The nascent field of proteomics was shown initially to be a very promising new technology for the detection of early-stage ovarian cancer (Petricoin, 2002). By profiling the patterns of thousands of proteins with a high degree of sensitivity and specificity, it was hoped that an accurate test, such as OvaCheck (Correlogic Systems, Rockville, MD), would reliably distinguish those with early ovarian cancer from unaffected women. Unfortunately, neither proteomics nor any other screening strategy is currently near implementation into routine clinical practice.

Physical Examination

For the near future, the only recommendation for prevention of ovarian cancer in asymptomatic women is an annual pelvic examination. There are no additional techniques that have proved to be effective in routine screening (American College of Obstetricians and Gynecologists, 2002). In general, the pelvic examination can detect ovarian cancer only occasionally, generally

when the disease is already in advanced stages.

Chemoprevention

Oral contraceptive use is associated with a 50-percent decreased risk of developing ovarian cancer. However, there is a short-term increased risk of developing breast cancer that should be considered when counseling patients (National Cancer Institute, 2007c).

Prophylactic Surgery

The only proven way to prevent ovarian cancer is surgical oophorectomy. As another possible site of disease among high-risk patients, the fallopian tubes also should be removed (Levine, 2003). In *BRCA1* or *BRCA2* mutation carriers, prophylactic bilateral salpingo-oophorectomy (BSO) may be performed on either completion of childbearing or at age 35 (American College of Obstetricians and Gynecologists, 1999). In these patients, the procedure is approximately 90 percent effective in preventing epithelial ovarian cancer (Kauff, 2002; Rebbeck, 2002). In women with HNPCC, the risk reduction approaches 100 percent (Schmeler, 2006).

The term *prophylactic* implies that the ovaries are normal at the time of removal. However, about 5 percent of *BRCA* mutation carriers undergoing prophylactic BSO will have an otherwise undetected, often microscopic ovarian cancer at the time of surgery (Lu, 2000). To account for this possibility, cytologic washings, peritoneal biopsies, and an omental sample should be collected routinely during surgery. In addition, the ovaries and tubes should be sectioned serially to identify occult disease (Powell, 2005). Typically, the excision, washings, and biopsies all can be completed by minimally invasive laparoscopic surgery.

Prophylactic BSO in young women will induce premature menopause and its associated effects of vasomotor and urogenital symptoms, decline in sexual interest, and osteoporosis (National Cancer Institute, 2007c). Estrogen-replacement therapy is used commonly to alleviate these symptoms but may be less effective than is often assumed (Madalinska, 2006). Overall, mainly because the favorable impact on reducing cancer worries, prophylactic BSO does not adversely affect quality of life (Madalinska, 2005).

In addition to preventing ovarian cancer, prophylactic BSO reduces a woman's risk of developing breast cancer by 50 percent (Rebbeck, 2002). Predictably, the protective effect is strongest among premenopausal women (Kramer, 2005).

Hysterectomy is mandatory when performing prophylactic BSO in women with the HNPCC syndrome because of coexisting endometrial cancer risks. In *BRCA* mutation carriers, it is not required but should be part of the preoperative discussion. Theoretically, not removing the uterus leaves some residual adnexal tissue that potentially could give rise to "ovarian" cancer. In practice, this concern is unproven. Relatively few reports have suggested an association between *BRCA* mutations and an increased risk of endometrial cancer. Mainly, these develop in patients taking tamoxifen for breast cancer treatment or breast cancer chemopreventionâ€”which is another factor to consider during counseling regarding possible hysterectomy (Beiner, 2006). Obviously, hysterectomy may add to the potential morbidity and postoperative recovery time. In summary, some patients will wish to proceed with hysterectomy, whereas others prefer a more conservative approach.

LOW-MALIGNANT-POTENTIAL TUMORS

About 10 to 15 percent of epithelial ovarian cancers have histologic and biologic features that are intermediate between clearly benign cysts and frankly invasive carcinomas. In general, these low-malignant-potential (LMP), also termed *borderline* , tumors are associated with risk factors that are similar to epithelial ovarian cancer (Huusom, 2006). Typically, they are not considered to be part of any of the hereditary breast-ovarian cancer syndromes. Although LMP tumors may develop at any age, on average, patients are in their mid-40sâ€”some 15 years younger than women with invasive ovarian carcinoma. For a variety of reasons, their diagnosis and optimal management frequently are problematic.

Pathology

Histologically, LMP tumors are distinguished from benign cysts by having at least two of the following features: nuclear atypia, stratification of the epithelium, formation of microscopic papillary projections, cellular pleomorphism, and mitotic activity (Fig. 35-2). Unlike invasive carcinomas, LMP tumors are characterized by the *absence* of stromal invasion. However, up to 10 percent of LMP tumors will exhibit areas of microinvasion, defined as foci measuring less than 3 mm in diameter and comprising less than 5

percent of the tumor (Buttin, 2002). Due to the subtle nature of many of these findings, it is challenging to diagnose an LMP tumor with certainty based on frozen section.

FIGURE 35-2

Clinical Features

Ovarian LMP tumors present in the same manner as other adnexal masses. Women may have pelvic pain, distention, or increasing abdominal girth. Alternatively, an asymptomatic mass may be palpated during a routine pelvic examination. These tumors are detected occasionally as an incidental finding during routine obstetric sonographic examination or at the time of cesarean delivery.

As with other ovarian tumors, size varies widely from a serous tumor of less than 1 cm to a mucinous tumor that is larger than 30 cm, filling the entire abdomen. Preoperatively, there is no pathognomonic sonographic appearance, and serum CA125 measurements are nonspecific. Depending on the clinical setting, computed tomographic (CT) scanning may be indicated to exclude ascites or omental caking, which would suggest typical ovarian cancer. Regardless, any woman with a suspicious adnexal mass should have it removed (see Chap. 9, Human Chorionic Gonadotropin).

Treatment

Surgery is the cornerstone management for LMP tumors. The operative plan will vary depending on circumstances, and patients should be counseled carefully beforehand. All women should be prepared for the operating room with the intent to perform complete ovarian cancer surgical staging or debulking, if necessary (see Management of Early-Stage Ovarian Cancer). In many cases, a laparoscopic approach is appropriate. If laparotomy is planned, then a vertical incision is selected to allow access to the upper abdomen and para-aortic nodes, if needed, for cancer staging. Premenopausal women who have not completed childbearing may undergo fertility-sparing surgery with preservation of the uterus and contralateral ovary (Zanetta, 2001). This is a reasonable approach even if the final diagnosis shows invasive stage I cancer (Schilder, 2002). In contrast, postmenopausal women should undergo hysterectomy with BSO.

During surgery, peritoneal washings should be collected immediately on entering into the abdomen, followed by exploration. The

ovarian mass should be removed intact and submitted to pathology for frozen section evaluation. However, it is almost impossible to know with certainty whether a patient has a benign adnexal mass, LMP tumor, or invasive ovarian cancer until final histologic slides have been reviewed (Houck, 2000). In those with LMP diagnosed intraoperatively, limited staging biopsies of the peritoneum and omentum should be considered. Additionally, the appendix also should be examined and potentially removed, especially if the tumor has mucinous histology. In the absence of enlarged nodes or a frozen section suggestive of frankly invasive disease, routine pelvic and para-aortic lymph node dissection may not be necessary (Rao, 2004).

Low-malignant-potential tumors are staged in the same manner as invasive ovarian cancer (see Table 35-5). For the most part, surgical staging has limited value in altering the prognosis of those with LMP tumors unless invasive cancer is diagnosed ultimately (Wingo, 2006). Although 97 percent of gynecologic oncologists advocate comprehensive surgical staging of LMP tumors, in current practice it is performed in only 12 percent of patients (Lin, 1999; Menzin, 2000). Usually this occurs if the diagnosis is not suspected intraoperatively, and a clinician is alerted when the final pathology report has been completed. In this circumstance, consultation with a gynecologic oncologist is recommended, but comprehensive surgical restaging is not necessarily required if the tumor appears confined to a single ovary. However, if a cystectomy has been performed, the risk of residual disease should prompt removal of the entire adnexa with washings and limited staging (Poncelet, 2006).

Table 35-5 FIGO Surgical Staging System for Ovarian Cancer

Stage	Surgical-Pathologic Findings
IA	Growth limited to one ovary
IB	Growth limited to both ovaries
IC	Tumor limited to one or both ovaries, but with disease on the surface of one or both ovaries; or with capsule(s) ruptured; or with malignant ascites or positive peritoneal washings
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic tissues
IIC	Tumor limited to the genital tract or other pelvic tissues, but with disease on the surface of one or both ovaries; or with capsule(s) ruptured; or with malignant ascites or positive peritoneal washings
IIIA	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal-peritoneal surfaces
IIIB	Abdominal implants less than 2 cm in diameter with negative nodes
IIIC	Abdominal implants at least 2 cm in diameter and/or positive pelvic, para-aortic, or inguinal nodes
IV	Distant metastases, including malignant pleural effusion or parenchymal liver metastases

FIGO = International Federation of Gynecology and Obstetrics. From Pecorelli, 1999, with permission.

For patients with stage IIâ€"IV disease, usually demonstrated by noninvasive implants (Fig. 35-3) or nodal metastases, the utility of adjuvant chemotherapy is speculative (Sutton, 1991). The most worrisome finding is the presence of invasive peritoneal implants. In general, these patients should be treated as if they have typical epithelial ovarian carcinoma, including de-bulking and postoperative chemotherapy.

Prognosis

The prognosis is excellent for patients with ovarian LMP tumors (Table 35-2). Overall, more than 80 percent have stage I disease, and if treated by hysterectomy and BSO, stage I tumors rarely, if ever, recur (Barnhill, 1995). Fertility-sparing surgery is associated with a 15-percent risk of relapse, usually in the contralateral ovary, but remains highly curable by reoperation and resection (Rao, 2005).

Table 35-2 Survival of Women with Ovarian Low-Malignant-Potential Tumors

Stage	5-Year Survival (%)
I	99
II	98
III	96
IV	77

From Trimble, 2002, with permission.

About 15 percent of LMP tumors are stage II and III disease, almost invariably of serous histology. Stage IV ovarian LMP tumors account for fewer than 5 percent of diagnoses and have the worst prognosis (Trimble, 2002). For advanced-stage tumors, the most reliable prognostic indicator is the presence of invasive peritoneal implants (Seidman, 2000).

Because of their indolent nature, symptomatic recurrence and death may develop as many as 20 years after therapy (Silva, 2006).

For most relapses, surgical excision is the most effective therapy. Chemotherapy typically is reserved for patients who develop ascites, have significant changes in the histologic features of the tumor, or demonstrate rapid tumor growth.

EPITHELIAL OVARIAN CANCER

Pathogenesis

There are at least three distinct tumorigenic pathways to account for the heterogeneity of epithelial ovarian cancer. First, relatively few cases seem to arise from an accumulation of genetic alterations leading to malignant transformation of benign cysts to LMP tumors and ultimately progressing to invasive ovarian carcinoma (Makarla, 2005). Typically, these invasive tumors are low grade and clinically indolent. In these tumors, K-*ras* oncogenic mutations occur early. The *ras* family of oncogenes includes K-*ras* , H-*ras* , and N-*ras* . Their protein products participate in cell cycle regulation and control of cell proliferation. As such, ras mutations have been implicated in carcinogenesis by their inhibition of cellular apoptosis and promotion of cellular proliferation (Mammas, 2005). In contrast, invasive cancers arising from LMP tumors have mutations in the *p53* tumor suppressor gene.

Second, about 5 to 10 percent of epithelial ovarian carcinomas result from an inherited predisposition. Women born with a *BRCA* mutation only require one "hit" to the other normal copy (allele) to "knock out" the *BRCA* tumor suppressor gene product. As a result, *BRCA* -related cancers develop about 15 years before sporadic cases. Thereafter, *BRCA* -related ovarian and peritoneal cancers appear to have a unique molecular pathogenesis, requiring *p53* inactivation to progress (Buller, 2001; Schorge, 2000). *p53* is a tumor suppressor gene that has been mapped to chromosome 17. Its protein product prohibits cells from entering subsequent stages of cell division and thereby halts uncontrolled tumor cell replication. Mutations in *p53* are linked with a variety of cancers. In fact, loss of *BRCA* and *p53* function has been detected prior to invasion, further supporting their importance as an early triggering event (Werness, 2000).

Third, the vast majority of carcinomas appear to originate de novo from ovarian surface epithelial cells that are sequestered in inclusion cysts within the ovarian stroma. Numerous inciting events and subsequent pathways have been proposed. For example, cyclic repair of the ovarian surface during long periods of repetitive ovulation requires abundant cellular proliferation. In these women, spontaneous *p53* mutations arising during the DNA synthesis that accompanies this proliferation appear to play a primary role in carcinogenesis (Schildkraut, 1997). Certainly, several developmental pathways are possible, stemming from early inactivation of innumerable genes.

Diagnosis

SIGNS AND SYMPTOMS

Ovarian cancer typically is portrayed as a "silent killer" without appreciable signs or symptoms until advanced disease is obvious clinically. This is a misconception. Actually, patients are often symptomatic for several months before the diagnosis, even with early-stage disease (Goff, 2000). The difficulty is in distinguishing these symptoms from those that occur normally in women.

In general, persistent symptoms that are more severe or frequent than expected and of recent onset warrant further diagnostic investigation. Women with malignant masses typically experience symptoms of notable severity 20 to 30 times per month. Commonly, increased abdominal size, bloating, urinary urgency, and pelvic pain are reported. Additionally, fatigue, indigestion, inability to eat normally, constipation, and back pain may be noted (Goff, 2004). Abnormal vaginal bleeding occurs rarely. Occasionally, patients may present with nausea, vomiting, and a partial bowel obstruction if carcinomatosis is particularly widespread. Unfortunately, many women and clinicians are quick to attribute such symptoms to menopause, aging, dietary changes, stress, depression, or functional bowel problems. As a result, weeks or months often pass before medical advice is sought or diagnostic studies are performed.

PHYSICAL EXAMINATION

A pelvic or pelvic-abdominal mass is palpable in most patients with ovarian cancer (Fig. 35-4). In general, malignant tumors tend to be solid, nodular, and fixed, but there are no pathognomonic findings that distinguish these growths from benign tumors. Paradoxically, a huge mass filling the pelvis and abdomen more often represents a benign tumor or low-grade malignancy. To aid surgical planning, a rectovaginal examination also should be performed. A woman with tumor impacted into the rectovaginal

septum may require a low anterior resection (see Section 43-19, Low Anterior Resection).

FIGURE 35-4

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photograph of a woman with a distended abdomen from a large ovarian mass.

The presence of a fluid wave or less commonly, flank bulging suggests the presence of significant ascites. In a woman with a pelvic mass and ascites, the diagnosis is ovarian cancer until proven otherwise. However, ascites without an identifiable pelvic mass suggests the possibility of cirrhosis or other primary malignancies such as gastric or pancreatic cancers. In advanced disease, examination of the upper abdomen usually reveals a central mass signifying omental caking.

Auscultation of the chest is also important because patients with malignant pleural effusions may not be overtly symptomatic. The remainder of the examination should include palpation of the peripheral nodes in addition to a general physical assessment.

LABORATORY TESTING

A routine complete blood count and metabolic panel often demonstrate a few characteristic features. For example, 20 to 25 percent of patients will present with thrombocytosis (platelet count > 400 $\times$ 10^9 /L) (Li, 2004). This is believed to result from malignant ovarian cells releasing cytokines that increase rates of platelet production. Hyponatremia, typically ranging between 125 and 130 mEq/L, is another common finding. In these patients, tumor secretion of a vasopressin-like substance can cause a clinical picture suggestive of a syndrome of inappropriate antidiuretic hormone (SIADH).

The serum CA125 test is integral to management of epithelial ovarian cancer. CA125 is a glycoprotein that is not produced by normal ovarian epithelium but may be produced by both benign and malignant ovarian tumors. This tumor marker is synthesized within affected ovarian epithelial cells and often secreted into cysts. In benign tumors, excess antigen is released into and may accumulate within cyst fluid. Hypothetically, abnormal tissue architecture associated with malignant tumors may allow antigen release into the vascular circulation (Verheijen, 1999).

In 90 percent of women presenting with malignant nonmucinous tumors, CA125 levels are elevated. However, preoperatively, it should not be used alone in the management of an adnexal mass (see Chap 9, Human Chorionic Gonadotropin). Half of stage I ovarian cancers will have a normal CA125 measurement (false negative). In contrast, an elevated value (false positive) may be

associated with a variety of common benign indications, such as pelvic inflammatory disease, endometriosis, leiomyomas, pregnancy, and even menstruation.

In postmenopausal women with a pelvic mass, a CA125 measurement may be helpful in predicting a higher likelihood of malignancy. This information is most useful when deciding whether to refer to a gynecologic oncologist (see Table 9-5). With mucinous tumors, the serum tumor markers cancer antigen 19-9 (CA-19-9) and carcinoembryonic antigen (CEA) may be better indicators of disease than CA125.

IMAGING

Sonography

To differentiate benign tumors and early-stage ovarian cancers, transvaginal sonography is typically the most useful imaging test (see Chap 2, Transvaginal Sonographic Endometrial Evaluation). In general, malignant tumors are multiloculated, solid or echogenic, large (>5 cm), and have thick septa with areas of nodularity (Figs. 35-5 and 35-6). Other features may include papillary projections or neovascularizationâ€”demonstrated by Doppler flow (Fig. 35-7). Although several presumptive models have been described in an attempt to distinguish benign masses from ovarian cancers preoperatively, none has been implemented universally (Timmerman, 2005; Twickler, 1999).

In patients with advanced disease, sonography is less helpful. The pelvic sonogram may be particularly difficult to interpret when a large mass encompasses the uterus, adnexa, and surrounding structures. Ascites, if present, is easily detected, but abdominal sonography has limited use.

Radiography

Every patient with suspected ovarian cancer should have a chest radiograph to detect pulmonary effusions or infrequently, pulmonary metastases. Rarely, a barium enema is helpful clinically in excluding diverticular disease or colon cancer or in identifying involvement of the rectosigmoid by ovarian cancer.

Computed-Tomography Scanning

The main advantage of computed tomography (CT) scanning is in treatment planning of women with advanced ovarian cancer. Preoperatively, it may detect disease in the liver, retroperitoneum, omentum, or elsewhere in the abdomen and thereby guide surgical cytoreduction (Fig. 35-8). However, CT scanning is not particularly reliable in detecting intraperitoneal disease smaller than 1 to 2 cm in diameter. As a result, almost invariably, tumor sites not detected by CT scan are identified intraoperatively. Moreover, the accuracy of CT scanning is poor for differentiating a benign ovarian mass from a malignant tumor when disease is limited to the pelvis. In these cases, transvaginal sonography is superior.

FIGURE 35-8

B.** More caudal axial CT reveals ascites **(curved arrows)** and marked omental caking **(arrows)** . *(Courtesy of Dr. Diane Twickler.)*

In general, other radiologic studies such magnetic resonance (MR) imaging, bone scans, and positron-emission tomography (PET) typically provide little valuable information preoperatively.

PARACENTESIS

A woman with a pelvic mass and ascites can be assumed to have ovarian cancer until proven otherwise surgically. Thus few patients require a diagnostic paracentesis to guide treatment. Moreover, this procedure typically is avoided diagnostically because cytologic results usually are nonspecific, and abdominal wall metastases may form at the needle entry site (Kruitwagen, 1996). However, paracentesis may be indicated for patients with ascites and the *absence* of a pelvic mass.

Role of the Generalist

There is often tremendous difficulty in distinguishing benign from malignant disease using the currently available diagnostic modalities. However, the presence of ascites, evidence of abdominal or distant metastases, and a family history of one or more first-degree relatives with ovarian or breast cancer should prompt consideration of referral. Additionally, premenopausal women with very elevated CA125 levels (i.e., >200 units/mL) and postmenopausal women with any elevation are at higher risk for malignancy (American College of Obstetricians and Gynecologists, 2002).

Ideally, for women with suspicious adnexal masses, surgery should be performed in a hospital with a pathologist on staff. Surgeons should be prepared to appropriately stage and potentially debulk ovarian cancer or consult a gynecologic oncologist. At minimum, samples for peritoneal cytology should be obtained when the abdomen is entered. The mass then should be removed intact through an incision that permits thorough staging and resection of possible sites of metastasis (American College of Obstetricians and

Gynecologists, 2002). If the intraoperative frozen section suggests malignancy, then surgical staging should be performed. However, in a study of more than 10,000 women with ovarian cancer, almost half of those with early-stage disease did not undergo the recommended surgical procedures (Goff, 2006).

Ultimately, following treatment, many patients with early-stage disease will return to their referring physician at some point during postoperative surveillance. Monitoring for relapse is often coordinated between the gynecologic oncologist and generalist in obstetrics and gynecology, especially if no chemotherapy is required following surgery.

Pathology

Although epithelial ovarian cancer is often thought of as a single entity, the different histologic types (Table 35-3) are variable in their behavior. Commonly, two or more cell types are mixed. Within each histologic type, tumors are further categorized as benign, borderline (low malignant potential), or malignant.

HISTOLOGIC GRADE

Mainly in early-stage disease, grade is an important prognostic factor that affects treatment planning (Morgan, 2006). Unfortunately, there is no universally accepted grading system for epithelial ovarian carcinoma. Instead, numerous different systems are used currently to assign grade. Most of these are based on architectural features and/or nuclear pleomorphism, with or without additional histopathologic criteria. In general, tumors are classified as grade 1 (well-differentiated), grade 2 (moderately differentiated), and grade 3 (poorly differentiated) lesions (Pecorelli, 1999).

HISTOLOGIC TYPE

Grossly, there are no distinguishing features among the types of epithelial ovarian cancer. In general, each has solid and cystic areas of varying sizes (Fig. 35-9).

SEROUS TUMORS

Adenocarcinoma

Half of all epithelial ovarian cancers have serous histology. Microscopically, the cells may resemble fallopian tube epithelium in well-differentiated tumors or anaplastic cells with severe nuclear atypia in poorly differentiated tumors (Fig 35-10). In well-differentiated tumors, the papillary structures are clearly formed within cystic areas, and psammoma bodies are identified frequently (Fig 35-11). During frozen section evaluation, psammoma bodies are essentially pathognomonic of an ovarian-type serous carcinoma. Often these tumors contain a variety of other cell types as a minor component (<10 percent) that may cause diagnostic problems but do not influence outcome (Lee, 2003).

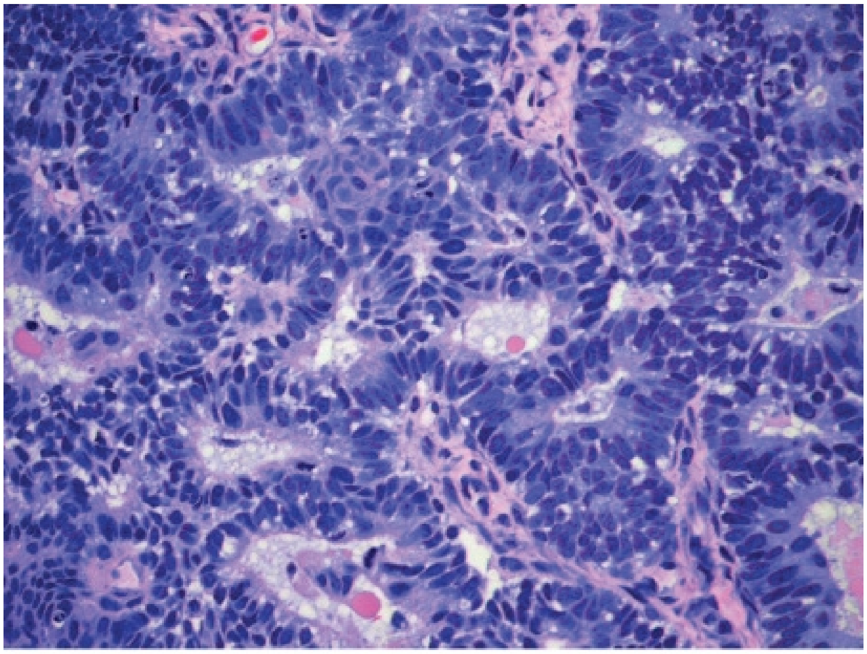
ENDOMETRIOID TUMORS

Adenocarcinoma

About 15 to 20 percent of epithelial ovarian cancers are endometrioid adenocarcinomas, the second most common histologic type (Fig. 35-12). However, the lower frequency results largely because poorly differentiated endometrioid and serous tumors cannot be distinguished easily, and such cases usually are classified as serous. As a result, well-differentiated endometrioid tumors are proportionally more common, which also may explain this tumor's overall relatively good prognosis.

FIGURE 35-12



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Photomicrograph of histologic specimen of endometrioid adenocarcinoma. Microscopically, well-differentiated endometrioid variants closely resemble adenocarcinomas of the endometrium, often exhibiting many of the same features (i.e., squamous differentiation). Psammoma bodies are present occasionally. Poorly differentiated ovarian endometrioid adenocarcinomas have a mainly solid pattern. The presence of residual microglandular areas distinguishes these tumors from serous or undifferentiated histologic types. *(Courtesy of Dr. Raheela Ashfaq.)*

In 15 to 20 percent of cases, there is a coexisting endometrial adenocarcinoma. This is usually regarded as a synchronous tumor, but metastasis from one site to the other is difficult to exclude (Soliman, 2004). It has been hypothesized that a mÃ¼llerian "field effect" accounts for these independently occurring, histologically similar tumors. In addition, many such patients are noted to have pelvic endometriosis.

Malignant Mixed MÃ¼llerian Tumor

These rare tumors represent less than 1 percent of ovarian cancers and are histologically similar to uterine primary tumors. By definition, they contain malignant epithelial and mesenchymal elements.

MUCINOUS TUMORS

Adenocarcinoma

About 5 to 10 percent of true epithelial ovarian cancers are mucinous adenocarcinomas. The frequency is usually overestimated because of undetected primary intestinal sites, such as the appendix or colon.Well-differentiated ovarian mucinous tumors closely resemble mucin-secreting adenocarcinomas of intestinal or endocervical origin (Fig. 35-13). Histologically, the distinction may be

impossible without clinical correlation (Lee, 2003).

FIGURE 35-13

Photomicrograph of histologic specimen of mucinous adenocarcinoma. *(Courtesy of Dr. Raheela Ashfaq.)*

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a clinical term used to describe the rare finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity surrounded by thin fibrous capsules. An ovarian mucinous carcinoma with ascites rarely results in this condition, and there is compelling evidence that ovarian mucinous tumors associated with pseudomyxoma peritonei are almost all metastatic rather than primary. As a result, appendiceal or other intestinal sites of origin should be excluded (Ronnett, 1997). The primary appendiceal tumor may be small relative to the ovarian tumor(s) and may not be appreciated macroscopically. Thus removal and thorough histologic examination of the appendix are indicated in all cases of pseudomyxoma peritonei.

If the peritoneal epithelial cells are benign or borderline-appearing, the condition is referred to as *disseminated peritoneal adenomucinosis.* Patients with this diagnosis have a benign or protracted, indolent clinical course (Ronnett, 2001). When the peritoneal epithelial cells appear malignant, the clinical course is invariably fatal.

Clear Cell Adenocarcinoma

Comprising 5 to 10 percent of epithelial ovarian cancers, clear cell adenocarcinomas are the most frequently associated with pelvic endometriosis. The appearance of these tumors is similar to that of clear cell carcinomas that develop sporadically in the uterus, vagina, and cervix.

Microscopically, both clear and "hobnail" cells are characteristic (Fig. 35-14). In clear cells, the visibly clear cytoplasm results from the dissolution of glycogen as the tissue specimen is prepared histologically. Hobnail cells have bulbous nuclei that protrude far into the cystic lumen beyond the apparent cytoplasmic limits of the cell (Lee, 2003).

TRANSITIONAL CELL TUMORS

Malignant Brenner Tumor

These rare ovarian cancers are characterized by the coexistence of a poorly differentiated transitional cell carcinoma and interspersed foci of a benign or borderline Brenner tumor. Microscopically, the transitional cell component resembles carcinomas arising from the urinary tract, often having squamous differentiation. Brenner tumors are characterized by having a dense, unusually abundant, fibrous stroma with embedded nests of transitional epithelium.

Transitional Cell Carcinoma

Accounting for fewer than 5 percent of ovarian cancers, these tumors are characterized histologically by the absence of a demonstrable Brenner component. Patients with transitional cell carcinoma have a worse prognosis than those with malignant Brenner tumors but better than those with other histologic types of epithelial ovarian cancer (Gershenson, 1993). Microscopically, it resembles a primary bladder carcinoma but has an immunoreactive pattern consistent with ovarian origin (Lee, 2003).

Squamous Cell Carcinoma

Rarely, tumors may be classified as primary squamous cell carcinoma. In fact, this is the newest category to be recognized. More commonly, squamous cell carcinomas arise from mature cystic teratomas (dermoid cysts) and are classified as malignant ovarian germ cell tumors (see Chap. 36). In other cases, ovarian endometrioid variants may have extensive squamous differentiation, or alternatively, metastases from a cervical primary are present.

Mixed Carcinoma

When more than 10 percent of an ovarian cancer exhibits a second cell type, it is classified as a mixed tumor. Common combinations include mixed clear cellâ€"endometrioid or serous-endometrioid adenocarcinomas.

Undifferentiated Carcinoma

Rarely, epithelial ovarian tumors are too poorly differentiated to be classified into any of the mÃ¼llerian types described earlier. Microscopically, the cells are arranged in solid groups or sheets with numerous mitotic figures and marked cytologic atypia. Typically, there are foci of mÃ¼llerian carcinoma, usually serous, within the tumor. Overall, undifferentiated carcinomas of the ovary have a very poor prognosis compared with the other histologic types (Silva, 1991).

Small Cell Carcinoma

These tumors are rare, extremely malignant, and consist of two subgroups. Most patients have a *hypercalcemic type,* which typically develops in young women during their 20s. Nearly all these tumors are unilateral, and two thirds are associated with elevated serum calcium levels that resolve postoperatively (Young, 1994). The *pulmonary type* resembles oat cell carcinoma of the lung and develops in older women, and half of cases have bilateral ovarian disease (Eichhorn, 1992). In general, patients with small cell carcinoma die within 2 years from rapid disease progression.

Primary Peritoneal Carcinoma

Up to 15 percent of typical epithelial ovarian cancers are actually primary peritoneal carcinomas that arise de novo from the lining of the pelvis and abdomen. In some cases, especially among *BRCA1* mutation carriers, independent malignant transformation occurs at multiple peritoneal sites simultaneously (Schorge, 1998). Clinically and histologically, these tumors are virtually indistinguishable from epithelial ovarian cancer. However, primary peritoneal carcinoma may develop in a woman years after undergoing BSO. If ovaries are still present, several criteria are required to make the diagnosis (Table 35-4). By far the most common variant is papillary serous, but any of the other histologic types are possible. In general, the staging, treatment, and prognosis of primary peritoneal carcinoma are the same as for epithelial ovarian cancer (Mok, 2003). The differential diagnosis mainly includes malignant mesothelioma.

Table 35-4 Criteria for Diagnosing Primary Peritoneal Carcinoma When Ovaries Are Present

1. Both ovaries must be normal in size or enlarged by a benign process
2. The involvement in the extraovarian sites must be greater than the involvement on the surface of either ovary
3. The ovarian tumor involvement must be either non- existent, confined to the ovarian surface epithelium without stromal invasion, or involving the cortical stroma with tumor size less than 5 x 5 mm.

Fallopian Tube Carcinoma

Although much rarer than epithelial ovarian cancer, fallopian tube carcinomas otherwise have many clinical similarities. For the most part, risk factors, histologic types, surgical staging, pattern of spread, treatment, and prognosis are comparable. To be considered a primary carcinoma of the fallopian tube, the tumor must be located macroscopically within the tube or its fimbriated end. Additionally, the uterus and ovary must not contain carcinoma, or if they do, it must be clearly different from the fallopian tube lesion (Alvarado-Cabrero, 2003).

Secondary Tumors

Malignant tumors that metastasize to the ovary almost invariably are bilateral. The term *Krukenberg tumor* refers to a metastatic mucinousâ€"signet ring cell adenocarcinoma of the ovaries that typically originates from primary tumors of the intestinal tract, characteristically the stomach (Fig. 35-15). Ovarian metastases often represent a late disseminated stage of the disease in which other hematogenously disseminated metastases are also found (Prat, 2003).

PATTERNS OF SPREAD

In general, epithelial ovarian cancers metastasize predominantly by *exfoliation* . Malignant cells are first released into the peritoneal cavity when a tumor penetrates through the ovarian capsule surface. By following the normal circulation of peritoneal fluid, implants then may develop anywhere in the abdomen. A unique characteristic of ovarian cancer is that metastatic tumors usually do not infiltrate visceral organs but exist as surface implants. As a result, aggressive debulking is possible with reasonable morbidity.

Because of its marked vascularity, the omentum is the most frequent location for disease spread and is often involved extensively with tumor (Fig. 35-16). Nodules are also commonly present on the undersurface of the right hemidiaphragm and small bowel serosa, but all intraperitoneal surfaces are at risk.

FIGURE 35-16

Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Lymphatic dissemination is the other primary mode of spread. Malignant cells may spread via channels that follow the ovarian blood supply along the infundibulopelvic ligament, terminating in para-aortic lymph nodes up to the level of the renal vessels. Other lymphatics pass laterally through the broad ligament and parametrium to the external iliac, obturator, and internal iliac nodal chains (see Fig. 38-16). Infrequently, metastases also may follow the round ligament to the inguinal nodes (Lee, 2003).

Direct extension of a progressively enlarging ovarian cancer may result in confluent tumor involvement of the pelvic peritoneum and adjacent structures, including the uterus, rectosigmoid colon, and fallopian tubes. Usually, this is associated with significant induration of the surrounding tissues.

In advanced disease, several liters of ascites may be present (Fig. 35-17). Generally, this is believed to result from either increased production of carcinomatous fluid or decreased clearance by lymphatic channel obstruction. Similarly, by traversing the diaphragm, a malignant pleural effusion may develop.

Hematogenous spread is atypical. In most cases, metastases to the liver or lung parenchyma, brain, or kidneys are observed in patients with recurrent disease, not at initial diagnosis.

STAGING

Ovarian cancer is staged surgically based on the typical patterns of spread (Table 35-5). Even if a tumor appears clinically to be confined to the ovary, in many cases it will have detectable metastases. Therefore, accurate surgical staging is crucial to guide treatment. About a third of patients have surgical stage I or II disease (Table 35-6).

Management of Early-Stage Ovarian Cancer

SURGICAL STAGING

When a malignancy appears clinically confined to the ovary, surgical removal and comprehensive staging should be performed. A third of patients who appear to have disease confined to the ovary will be "up-staged" by surgical staging and require postoperative chemotherapy. In those with stage IA or IB, grade 1 or 2 epithelial ovarian carcinoma, further treatment is unnecessary (Young, 1990).

Typically, the abdominal incision must be adequate to identify and resect any disease that may have been missed on physical examination or imaging tests. The operation begins by aspirating free ascitic fluid or collecting peritoneal washings, followed by visualization and palpation of all peritoneal surfaces. The infracolic omentum should be removed or at least biopsied (see Section 43-12, Omentectomy). Next, an extrafascial (simple) hysterectomy and BSO are performed (see Section 41-19, Hysterectomy). In the absence of gross extraovarian disease, peritoneal biopsies are obtained, along with a biopsy or scraping of the right diaphragm. Finally, a pelvic and infrarenal para-aortic lymphadenectomy is completed (see Sections 43-9, Pelvic Lymphadenectomy and 43-10, Para-Aortic Lymphadenectomy) (Whitney, 2005).

Laparoscopic staging is particularly valuable as a primary treatment in women who have an apparent stage I ovarian cancer. In those with unstaged disease, patients may have completion of their staging by laparoscopy. In general, all the required procedures can be performed safely with laparoscopy (Chi, 2005). The main putative benefits are a shorter hospital stay and quicker recovery (Tozzi, 2004). However, there is a learning curve for lymphadenectomy using this emerging, minimally invasive technique. Nodal counts may be inferior, and exploration of the abdomen is unavoidably limited. For a variety of reasons, including the presence of adhesions and/or unanticipated metastatic disease, up to 20 percent of laparoscopic cases will be converted to laparotomy (Spirtos, 2005).

FERTILITY-SPARING MANAGEMENT

Since about 10 percent of epithelial ovarian cancers develop in women younger than 40 years of age, fertility-sparing surgery may be an option in selected patients when disease appears confined to one ovary. Although many patients will be up-staged, those with surgical stage I disease have an excellent long-term survival with unilateral adnexectomy. In some cases, postoperative chemotherapy may be required, but patients usually will retain their ability to conceive and ultimately carry a pregnancy to term (Schilder, 2002).

ADJUVANT CHEMOTHERAPY

In general, patients with stage IA or IB, grade 3 epithelial ovarian cancer and all patients with stage IC and II tumors should be treated with three to six cycles of carboplatin (Paraplatin, Bristol-Myers Squibb, Princeton, NJ) and paclitaxel (Taxol, Bristol-Myers Squibb, Princeton, NJ) chemotherapy (Morgan, 2006; Trimbos, 2003). In a phase III GOG trial (protocol 157), women with early-stage disease were randomly assigned to either three or six cycles of this combination. Overall, three cycles resulted in a comparable relapse rate as six cycles but was associated with less toxicity (Bell, 2006).

Despite chemotherapy, more than 20 percent of women with early-stage disease develop recurrences within 5 years, suggesting the need for a better treatment strategy. In response, the GOG is currently performing a randomized phase III trial of three cycles of adjuvant carboplatin and paclitaxel chemotherapy followed by observation or weekly paclitaxel for 24 weeks (protocol 175).

SURVEILLANCE

After completion of treatment, patients with early-stage ovarian cancer may be followed every 2 to 4 months for the first 2 years, then twice yearly for an additional 3 years, and then annually. At each visit, complete physical and pelvic examinations should be performed. In addition, a serum CA125 determination is indicated if the level was elevated initially. If warranted clinically, imaging tests also may be helpful to exclude recurrent disease (Morgan, 2006).

Management of Advanced Ovarian Cancer

Approximately two thirds of patients will have stage IIIâ€“IV disease. Thus, multimodality therapy is particularly important to achieve the most successful outcome (Earle, 2006). Ideally, surgical cytoreduction is performed initially to remove all gross disease, that is, optimal tumor debulking. Surgery is followed by six courses of platinum-based chemotherapy. However, some women will not be appropriate candidates for primary surgery because of their medical condition, and others will have unresectable tumor. To balance all clinical factors effectively, each patient should be assessed individually before embarking on a treatment

strategy.

PRIMARY CYTOREDUCTIVE SURGERY

Residual Disease

Since the initial report by Griffiths in 1975 suggested the value of debulking, its value largely has been assumed. Numerous retrospective studies subsequently have supported the apparent survival advantage in women with advanced ovarian cancer if less than 2 cm of residual disease can be achieved by cytoreduction. Specifically, *2 cm of residual disease* describes a surgical result in which none of multiple remaining areas of tumor individually measures greater than 2 cm. Additional incremental improvements in survival have been demonstrated if residual disease is less than 1.5 cm, less than 1 cm, or less than 0.5 cm. Longest survival durations are reported if no residual disease remains at the surgery completion (Eisenkop, 1998). By definition, for patients to be considered "optimally debulked", that is, to display *minimal residual disease,* they must have areas of residual tumor that measure less than 1 cm.

There are several reasons why resecting ovarian cancer implants is believed to prolong survival. First, surgery removes large volumes of chemoresistant tumor cell clones. Second, the removal of necrotic masses improves drug delivery to remaining well-vascularized cells. Third, small residual tumor implants should be faster growing and therefore more susceptible to chemotherapy (see Chap. 27). Fourth, reducing the numbers of cancer cells should require fewer cycles of chemotherapy and reduce the chances of chemoresistance. Finally, removal of bulky disease potentially enhances the immune system.

Whether any of these supposed advantages to debulking are actually clinically relevant is debatable (Covens, 2000). However, because of the presumed benefits, primary surgical cytoreduction generally is performed whenever feasible clinically. Since the goal is maximal resection of ovarian cancer and all metastatic disease, laparoscopic surgery has virtually no role. Instead, a variety of procedures may be required to achieve minimal residual disease.

Surgical Approach to Cytoreductive Surgery

Typically, a vertical incision is recommended to provide access to the entire abdomen. Patients with advanced disease do not require peritoneal washings or cytologic assessment of fluid, but often several liters of ascites will need to be evacuated to improve access. Next, the abdomen is explored carefully to quickly determine if optimal debulking is feasible. Limited surgical evaluation is preferable to extensive debulking if it is obvious that tumors larger than 2 cm will be left behind. If hysterectomy and BSO are not possible, a biopsy of the ovary and sampling of the endometrium must be performed. However, if disease is resectable, then surgery should begin with the least complicated procedure.

Often, an infracolic omentectomy can be performed and extended easily (i.e., supracolic), if necessary, to encompass the disease (see Section 43-12, Omentectomy). A frozen section then may be obtained to confirm the presumptive diagnosis of epithelial ovarian cancer. The pelvis is assessed next. Usually, a total abdominal hysterectomy and BSO are sufficient. However, when the tumor is confluent or invading the rectosigmoid, an en bloc resection (see Section 43-11, En Bloc Pelvic Resection), low anterior resection (see Section 43-19, Low Anterior Resection), or modified posterior pelvic exenteration (see Section 43-5, Posterior Pelvic Exenteration) may be required.

Patients with abdominal tumor nodules that are less than 2 cm in size (apparent stage IIIB) must have bilateral pelvic and para-aortic node biopsies (see Sections 43-9, Pelvic Lymphadenectomy and 43-10, Para-Aortic Lymphadenectomy). In patients with stage IV disease and those with abdominal tumor nodules at least 2 cm in size (already stage IIIC disease), nodal dissection is not necessarily required. Histologically confirmed metastatic lymph nodes eliminates the need for further sampling (Whitney, 2005). However, if sampling is not performed, a significant percentage of patients will have unrecognized macroscopic nodal disease (Eisenkop, 2001).

To achieve optimal surgical cytoreduction also may require a variety of other procedures, including splenectomy (see Section 43-13, Splenectomy), diaphragm stripping/resection (see Section 43-14, Diaphragmatic Surgery), and small or large bowel resection (see Sections 43-16, Large Bowel Resection and 43-18, Small Bowel Resection). For diagnostic purposes, and since it is a frequent site of disease, an appendectomy is also commonly included (see Section 43-21, Appendectomy).

INTERVAL CYTOREDUCTIVE SURGERY

Many patients do not undergo initial optimal surgical debulking (Everett, 2006). In some cases, imaging studies may suggest unresectable disease. Other patients may be too medically compromised, may not have received initial care by a gynecologic oncologist, or may have large-volume "suboptimal" residual disease despite attempted debulking. In such circumstances, an "interval" cytoreductive surgery may be an option after three to four courses of chemotherapy have shrunk the tumor.

PRIMARY CHEMOTHERAPY

Advanced ovarian cancer is considered to be relatively sensitive to cytotoxic agents. Largely due to recent advances in identifying active drugs, the duration of survival among patients has increased over the past two decades. Despite such improvements, fewer than 20 percent will be cured.

Intravenous Chemotherapy

Platinum-based chemotherapy is the foundation of systemic treatment of ovarian cancer. In two large collaborative group trials (GOG protocol 158 and Arbeitsgemeinschaft GynÃ¤kologische Onkologie [AGO] protocol OVAR-3), the combination of carboplatin and paclitaxel was easier to administer, similarly efficacious, and less toxic (du Bois, 2003; Ozols, 2003). As a result, the most widely used intravenous (IV) regimen in the United States is six courses of carboplatin and paclitaxel. If additional cycles are required to achieve clinical remission, this suggests relative tumor chemoresistance and usually leads to an earlier relapse. In Europe, single-agent carboplatin is often used based on two large phase III trials of the International Collaborative Ovarian Neoplasm (ICON) group, which did not detect a survival advantage for combination chemotherapy (The ICON Collaborators, 1998; The ICON Group, 2002).

Although the combination of carboplatin and paclitaxel undoubtedly is effective, the addition of a third cytotoxic agent has been postulated to further improve outcome. Unfortunately, the preliminary analysis of a recent phase III trial failed to demonstrate any superiority compared with the control group (du Bois, 2006).

Intraperitoneal Chemotherapy

In January 2006, the National Cancer Institute issued a rare clinical announcement encouraging the use of intraperitoneal (IP) chemotherapy (National Cancer Institute, 2007b). This coincided with the publication of results from a phase III GOG trial (protocol 172) of optimally debulked stage III ovarian cancer patients who were randomly assigned to receive either intravenous or combination IV/IP paclitaxel and cisplatin chemotherapy (Table 35-7). The median duration of overall survival was 66 months in the IV/IP group compared with 50 months in the intravenous treatment group (Armstrong, 2006). Despite this dramatic improvement in survival, many clinicians still consider IP chemotherapy to be an experimental treatment (Gore, 2006).

Table 35-7 Intraperitoneal Chemotherapy Regimen for Ovarian Cancer

Day 1	Paclitaxel 135 mg/m^2 IV over 24 h
Day 2	Cisplatin 100 mg/m^2 IP
Day 8	Paclitaxel 60 mg/m^2 IP

IV = intravenous; IP = intraperitoneal. From Armstrong, 2006, with permission.

The theoretical advantages of IP chemotherapy are dramatic (see Chap. 27, Route of Administration). In general, epithelial ovarian cancer spreads mainly along peritoneal surfaces. In postoperative patients with minimal residual disease, a much higher dose of chemotherapy can be achieved at the tumor site by administration directly into the abdomen (Alberts, 1996; Markman, 2001).

Obviously, not every woman with advanced ovarian cancer is an appropriate candidate for IP chemotherapy. Stage IV patients and those with large-volume residual disease are least likely to benefit. In addition, toxicity is generally higher with IP therapy, catheter-related problems are common, and the true survival advantage remains controversial (Walker, 2006). Regardless, the current consensus is that IP therapy certainly should be considered for low-volume, optimally debulked stage III disease (Morgan, 2006). However, the choice to receive or not receive IP chemotherapy ultimately should be a decision made by an informed patient (Alberts, 2006).

In light of the National Cancer Institute clinical announcement and ensuing debate, new IP regimens are being tested currently. Phase I trials of new IP combinations are being conducted in an effort to develop a regimen with more acceptable toxicity. For example, phase I trials of dose-escalating IP carboplatin are underway through the GOG. It is anticipated that these data will shape future applications of ovarian cancer IP therapy.

Management of Patients in Remission

In most women with advanced ovarian cancer, the combination of surgery and platinum-based chemotherapy will result in clinical remission (normal examination, CA125 levels, and CT scan findings). However, up to 80 percent will relapse eventually and die from disease progression. Lower CA125 levels (i.e., single-digit values) generally are associated with fewer relapses and longer survival (Juretzka, 2007). Since most patients achieving remission will have residual, clinically occult, drug-resistant cells, several options are appropriate to consider. Unfortunately, there is no solid proof that any intervention is beneficial.

SURVEILLANCE

After completion of treatment, patients should be followed regularly with examinations and CA125 determinations, as in early-stage disease. To monitor advanced ovarian cancer patients, imaging tests may be indicated more frequently. In general, clinicians should maintain a more heightened suspicion for relapse.

SECOND-LOOK SURGERY

The "gold standard" for identifying residual disease is a second-look laparotomy. In general, the main indications are to assess the completeness of response and to resect residual tumor.

A true second-look operation consists of several steps. First, ascitic fluid or cytologic washings should be collected unless biopsy-proven disease is discovered. Second, all peritoneal surfaces must be examined visually, including direct inspection of the diaphragm, to aid removal of any suspicious nodules, adhesions, or tumors. Third, in the absence of gross disease, routine biopsies are performed from peritoneal surfaces and residual omentum. Finally, pelvic and para-aortic nodal sampling is required unless it was performed initially and no disease was found (Whitney, 2005). Second-look laparoscopy is an acceptable, less morbid alternative for selected patients (Husain, 2001; Littell, 2006).

For numerous reasons, however, neither type of second-look surgery is performed routinely. Although nonrandomized studies occasionally have reported a clinical advantage to identifying patients with residual disease, two European multicenter randomized trials of second-look laparotomy failed to demonstrate survival benefit (Luesley, 1988; Nicoletto, 1997). In addition, a recent nonrandomized comparison of patients from a prior GOG trial who had undergone second-look surgery was not associated with longer survival (Greer, 2005).

In summary, second-look laparotomy serves primarily as a useful early endpoint in assessing the effectiveness of treatment within an experimental protocol. Otherwise, no prospective clinical trials have demonstrated a survival advantage. Second-look surgery does have prognostic value because a procedure that reveals no recurrent disease is associated with an improved survival rate. In summary, the additional morbidity and cost must be weighed against the expected benefit for an individual patient (American College of Obstetricians and Gynecologists, 1996).

MAINTENANCE CHEMOTHERAPY

There is limited evidence to suggest any advantage for additional treatment in women who achieve clinical remission after six courses of platinum-based chemotherapy. However, because of the known high rate of recurrence, several agents have been tested as maintenance therapy, also termed *consolidation therapy,* in nonrandomized studies. Of these agents, lower-dose paclitaxel or CT-2103 (Xyotax, a conjugated paclitaxel with a more favorable toxicity profile, Cell Therapeutics, Seattle, WA) are being evaluated to determine if they actually can reduce the death rate compared with no maintenance therapy. The GOG currently is conducting a phase III trial of these drugs in women with advanced ovarian cancer who achieved a clinical remission after standard platinum-based chemotherapy (protocol 212).

In the meantime, monthly paclitaxel for 12 cycles is the only maintenance therapy to demonstrate any clinical advantage. Interestingly, this benefit appeared to be limited mainly to patients with the lowest CA125 levels and presumably, the lowest tumor

burden at study entry (Markman, 2006). In addition, cumulative toxicity, most notably neuropathy, can be substantialâ€”resulting in frequent dose reductions (Markman, 2003).

Radiation Therapy

In the United States, patients in remission after primary therapy are rarely treated with whole abdominal radiotherapy because of unproven benefit and fears of excessive toxicity such as radiation enteritis (Sorbe, 2003). However, the long-term effectiveness of this consolidation strategy is comparable with that achieved in women treated with other modalities. As a result, it may be considered for selected patients with microscopic disease detected at second-look surgery (Morgan, 2006). In general, this practice is much more common in Europe (Petit, 2007).

Prognostic Factors

The overall 5-year survival rate of all stages of epithelial ovarian cancer is 50 percent, far lower than uterine (80 percent) or cervical cancer (70 percent). Surgical stage is the most important variable, but relative survival also varies by age (Table 35-8). Specifically, women younger than 65 years are approximately twice as likely to survive 5 years following diagnosis. Interestingly, BRCA mutation carriers also have a better prognosis chiefly due to increased platinum sensitivity (Cass, 2003). Additional prognostic factors are shown in Table 35-9.

Table 35-8 Epithelial Ovarian Cancer 5-Year Survival Rates for Each FIGO Stage (*n* = 4,911 Patients)

Stage	5-Year Survival (%)
I	86
II	70

Table 35-9 Prognostic Factors for Ovarian Cancer
Good performance status
Cell type other than mucinous and clear cell
Well-differentiated tumor
Smaller disease volume prior to any surgical debulking
Absence of ascites
Smaller residual tumor following primary cytoreductive surgery

From National Cancer Institute, 2007a, with permission.

Due to several advances, there has been recent improvement in the overall survival of women with ovarian cancer (Chan, 2006). By employing a more aggressive surgical approach, the rate of optimal primary cytoreduction has been increased (Chi, 2004). The activity of paclitaxel in combination with a platinum agent also has improved survival rates for many. The recent use of IP chemotherapy demonstrated the longest duration of survival for stage III patients among all randomized phase III trials conducted by the GOG. Regardless, treatment of recurrent disease is particularly important because most patients will relapse ultimately.

Management of Recurrent Ovarian Cancer

Gradual elevation of the CA125 level is usually the first sign of relapse. Tamoxifen may be administered frequently when this is the only evidence for disease progression because it has some activity in treating recurrent disease, and toxicity is minimal. Alternatively, patients may be offered participation in a clinical trial, started on cytotoxic chemotherapy, or observed until clinical symptoms arise. Without treatment, the recurrence usually will become obvious clinically within 2 to 6 months. Almost invariably, the tumor will be located somewhere within the abdomen.

Women who progress during primary chemotherapy are classified as having *platinum-refractory disease.* Those who relapse within 6 months have *platinum-resistant ovarian cancer* (National Cancer Institute, 2007d). In general, patients in either category have a dismal prognosis, and palliative nonplatinum chemotherapy is effectively the only option. Participation in an experimental clinical trial should be offered whenever possible. Otherwise, response rates typically range from 10 to 15 percent using conventional cytotoxic drugs such as paclitaxel, pegylated liposomal doxorubicin (Doxil, Ortho Biotech Products, Bridgewater, NJ), docetaxel (Taxotere, Sanofi-Aventis, Bridgewater, NJ), topotecan (Hycamtin, GlaxoSmithKline, Philadelphia, PA), or gemcitabine (Gemzar, Eli Lilly, Indianapolis, IN).

Women who relapse more than 6 to 12 months after completion of primary therapy are considered *platinum-sensitive.* These patients, especially those in prolonged remission beyond 18, 24, or 36 months, have the greatest number of potential options, which are subsequently discussed (Morgan, 2006).

SECONDARY CYTOREDUCTIVE SURGERY

Although patient selection is somewhat arbitrary, the best candidates for secondary cytoreductive surgery have (1) platinum-sensitive disease, (2) a prolonged disease-free interval, (3) a solitary site of recurrence, and (4) no ascites (Chi, 2006). To achieve a maximal survival benefit, debulking must result in minimal residual disease (Harter, 2006). However, about half of patients will be explored without achieving this goal. Further, as in primary surgical cytoreduction, the overall survival benefit of this approach has never been studied in a randomized clinical trial.

SALVAGE CHEMOTHERAPY

Regardless of whether patients undergo additional surgery, retreatment with a platinum drug is the treatment of choice for patients with recurrent platinum-sensitive ovarian cancer. Carboplatin combined with either paclitaxel or gemcitabine has demonstrated superiority compared with carboplatin alone (Parmar, 2003; Pfisterer, 2006). However, giving these drugs sequentially as single agents might be equally successful and less toxic (National Cancer Institute, 2007d). Thereafter, pegylated liposomal doxorubicin may be the most appropriate choice (Gordon, 2001). Topotecan and docetaxel are other commonly used agents. Recently, the biologic agent bevacizumab (Avastin, Genentech, South San Franscisco, CA) also has demonstrated promising activity (Monk, 2006).

Regardless of which regimen is selected initially, re-evaluation usually should follow two to three cycles of chemotherapy to determine the clinical benefit (Morgan, 2006). Nonresponders should be changed to a different regimen that may be more efficacious.

Since the type of chemotherapy is based on overall response rates for all the histologic variants of epithelial ovarian cancer, it would seem plausible that targeting therapy for an individual patient's disease might be more effective than selecting a drug empirically. In vitro chemosensitivity testing is used occasionally for this purpose. In principle, different agents are tested against the patient's tumor, and the chemotherapeutic drug demonstrating the best response should result in a better outcome. Unfortunately, this approach lacks demonstrable clinical efficacy (Morgan, 2006).

Palliation of End-Stage Ovarian Cancer

During treatment, intermittent episodes of partial small and large bowel obstruction are common. However, at some point patients with recurrent disease will develop worsening symptoms that warrant re-evaluation of their overall treatment strategy.

Bowel obstruction that does not resolve with nasogastric suction can be managed in two very different ways. Frequently, a patient may desire an aggressive approach with surgical intervention, initiation of total parenteral nutrition (TPN), and continued

chemotherapy. Ideally, a colostomy (see Section 43-15, Colostomy), ileostomy (see Section 43-17, Ileostomy), or intestinal bypass (see Section 43-20, Intestinal Bypass) will return reasonably normal bowel function. Unfortunately, a satisfactory surgical result is often impossible because of multiple sites of partial or complete obstruction. In addition, successful palliation rarely is achieved when the transit time is prolonged by diffuse peritoneal carcinomatosis or when the anatomy requires a bypass that results in the short bowel syndrome (National Cancer Institute, 2007d). Further, recovery often is complicated by an enterocutaneous fistula, reobstruction, or other morbid event (Pothuri, 2004). For some patients, the best approach to managing a refractory bowel obstruction may be placement of a palliative gastrostomy tube, IV hydration, and hospice care. The final decision about how to proceed should be based on a frank discussion. Topics include treatment options, the natural history of progressive ovarian cancer, and the realistic possibility of any further disease response by switching to a different therapy.

Another common scenario is a woman with symptomatic, rapidly reaccumulating ascitic fluid. This may be alleviated by repeated paracenteses or placement of an indwelling peritoneal catheter (Pleurx, Denver Biomedical, Golden, CO). Similarly, a refractory malignant pleural effusion usually can be managed by thoracentesis, pleurodesis, or indwelling peritoneal catheter placement.

Although these procedures and others may be appropriate in selected patients, the inability to halt disease progression should be acknowledged. In addition, any intervention has the potential to result in an unanticipated catastrophic complication. Overall, palliative procedures are used most compassionately when incorporated into the overall treatment plan. For example, in a woman with stable disease and normal renal function, tumor-induced ureteral compression and hydronephrosis does not necessarily require stent placement or a nephrostomy tube.

All patients deserve a positive, hopeful, but honest approach to the management of progressive, incurable disease. Often there are unrealistic expectations about the benefit of palliative chemotherapy, but emotionally, it may be preferable to no treatment (Doyle, 2001). There is no substitute for mutual trust in the doctor-patient relationship when making sound decisions aimed at improving the quality of life of women with end-stage ovarian cancer.

OVARIAN GERM CELL AND SEX CORDÂ€“STROMAL TUMORS: INTRODUCTION

Three major categories account for virtually all malignant ovarian tumors. Organization of these groups is based on the anatomic structures from which the tumors originate (Fig. 36-1). Epithelial ovarian cancers account for 90 to 95 percent of malignant ovarian tumors (see Chap. 35). Germ cell and sex cordâ€“stromal ovarian tumors account for the remaining 5 to 10 percent and have unique qualities that require a special management approach (Quirk, 2005).

FIGURE 36-1

Origins of the three main types of ovarian tumors. *(From Chen, 2003, with permission.)*

MALIGNANT OVARIAN GERM CELL TUMORS

Germ cell tumors arise from the ovary's germinal elements and comprise a third of all ovarian neoplasms. The mature cystic teratoma, also called *dermoid cyst,* is by far the most common subtype. This accounts for 95 percent of all germ cell tumors and is clinically benign (see Chap. 9, Mature Cystic Teratoma (Benign Cystic Teratoma or Dermoid Cyst)). In contrast, malignant germ cell tumors comprise fewer than 5 percent of malignant ovarian cancers in Western countries and include *dysgerminoma, yolk sac tumor, immature teratoma,* and other less common types.

Three features typically distinguish malignant germ cell tumors from epithelial ovarian cancers. First, individuals typically present

at a younger age, usually in their teens or early twenties. Second, most have stage I disease at diagnosis. Third, prognosis is excellentâ€”even for those with advanced diseaseâ€”due to exquisite tumor chemosensitivity.

Fertility-sparing surgery is the primary treatment for women seeking future pregnancy, and most will not require postoperative chemotherapy.

Epidemiology

The age-adjusted incidence of malignant ovarian germ cell tumors in the United States is much lower (0.4 per 100,000 women) than that of epithelial ovarian carcinomas (15.5) but twice that of sex cordâ€"stromal tumors (0.2) (Quirk, 2005). Malignant germ cell tumors generally are not thought to be inherited, but familial cases are reported rarely (Galani, 2005; Stettner, 1999).

These tumors are the most common ovarian malignancies diagnosed during childhood and adolescence, although only 1 percent of all ovarian cancers develop in these age groups. At age 20, however, the incidence of epithelial ovarian carcinoma begins to rise and exceeds that of germ cell tumors (Young, 2003).

Diagnosis

SIGNS AND SYMPTOMS

The signs and symptoms associated with these tumors are varied, but in general, most arise from tumor growth and hormones the tumor produces. Subacute abdominal pain is the most common symptom and reflects rapid growth of a large, unilateral tumor undergoing capsular distention, hemorrhage, or necrosis. In addition, cyst rupture, torsion, or intraperitoneal hemorrhage leads to an acute abdomen in 10 to 20 percent of patients (De Backer, 2006). In more advanced disease, ascites may develop and cause abdominal distention. Because of the hormonal changes that frequently accompany these tumors, menstrual irregularities also may develop. Although most individuals note one or more of these symptoms, one quarter of individuals are asymptomatic, and a pelvic mass is noted unexpectedly during physical or sonographic examination (Curtin, 1994).

HISTORY

Individuals typically seek care within 1 month of the onset of abdominal complaints, although some note subtle waxing and waning symptoms for more than a year. Most young women with these tumors are nulligravidas with normal periods, but as discussed later, individuals with dysgenetic gonads are at significant risk for development of these tumors (Curtin, 1994). Therefore, adolescents who present with pelvic masses and delayed menarche should be evaluated for gonadal dysgenesis (see Chap. 16, Chromosomal Defects).

DIFFERENTIAL DIAGNOSIS

Vague pelvic symptoms are common during adolescence due to initiation of ovulation and menstrual cramping. As a result, early symptoms may be dismissed. Moreover, young girls may be silent about changes to their normal pattern, fearful of their significance. Early symptoms can be misinterpreted as those of pregnancy and acute pain may be confused with appendicitis.

Finding an adnexal mass is the first diagnostic step. In most cases, sonography can display those qualities which typically characterize benign and malignant ovarian masses adequately (see Table 9-4). Functional ovarian cysts are vastly more common in young women, and once identified as hypoechoic, smooth-walled cysts may be observed by sonography. In contrast, malignant germ cell tumors are usually larger with solid components. Elevated serum human chorionic gonadotropin (hCG) or alpha-fetoprotein (AFP) tumor markers may narrow the diagnostic possibilities and suggest the potential need for surgical staging.

PHYSICAL EXAMINATION

Distinguishing physical findings typically are lacking in individuals with malignant germ cell tumors. A palpable mass on pelvic examination is the most common finding. In children and adolescents, however, completing a comprehensive pelvic or transvaginal sonographic examination can be difficult and may lead to diagnostic delay (see Chap. 14, Ovarian Tumors). Accordingly, premenarchal patients may require examination under anesthesia to assess a suspected adnexal tumor adequately. The remainder of the physical examination should search for signs of ascites, pleural effusion, and organomegaly.

LABORATORY TESTING

Patients with a suspected malignant germ cell tumor should have serum hCG and AFP tumor marker determination, a complete blood count, and liver function tests drawn before treatment. Alternatively, the appropriate tumor marker determinations may be ordered in the operating room if the diagnosis was not suspected previously (Table 36-1). Preoperative karyotyping of young women with primary amenorrhea and a suspected germ cell tumor can clarify whether both ovaries should be removed, as in the case of women with gonadal dysgenesis (Hoepffner, 2005).

Table 36-1 Serum Tumor Markers in Malignant Ovarian Germ Cell Tumors

Histology	AFP	hCG
Dysgerminoma	â€“	Â±
Yolk sac tumor	+	â€“
Immature teratoma	Â±	â€“
Choriocarcinoma	â€“	+
Embryonal carcinoma	+	+
Mixed germ cell tumor	Â±	Â±
Polyembryoma	Â±	Â±

AFP = alphafetoprotein; hCG = human chorionic gonadotropin.

IMAGING

Mature cystic teratomas (dermoid cysts) usually display characteristic features when imaged with sonography or computed tomographic (CT) scanning (see Chap. 9, Pathology). However, the appearance of malignant germ cell tumors differs, and a multilobulated complex ovarian mass is typical (Fig. 36-2). Moreover, prominent blood flow in the fibrovascular septa may be seen using color-flow Doppler sonography and suggests the likelihood of malignancy (see Fig. 35-6). (Kim, 1995). Additional preoperative CT scanning or magnetic resonance (MR) imaging is not mandatory because the abdomen will be explored during surgery. However, chest radiography is warranted to search for tumor metastases in the lungs or mediastinum.

Computed tomographic (CT) scan of a germ cell tumor.

DIAGNOSTIC PROCEDURES

Sonographically or CT-guided percutaneous biopsy has no role in the management of patients with an ovarian mass suspicious for malignancy. Surgical resection is required for definitive tissue diagnosis, staging, and treatment. The surgeon should request a frozen section evaluation to confirm the diagnosis, but discrepancies between frozen-section interpretations and the final paraffin histology are commonplace (Kusamura, 2000). In addition, specific immunostaining is often required to resolve equivocal cases (Cheng, 2004; Ramalingam, 2004; Ulbright, 2005).

Role of the Generalist

Most patients will be seen initially by a generalist in obstetrics and gynecology. Initial symptoms may point to the more common functional ovarian cyst. Persistent symptoms or an enlarging pelvic mass, however, should prompt sonographic evaluation. If a complex ovarian mass with solid features is noted in this young age group, then measurement of serum hCG and AFP levels and referral to a gynecologic oncologist for primary surgical management should ensue.

When a specialist is unavailable or the diagnosis is not anticipated beforehand, intraoperative decisions are crucial to treat the patient adequately without compromising future fertility. Peritoneal washings are obtained and set aside before proceeding with dissection of any suspicious adnexal mass. The washings can be discarded later if malignancy is excluded. Initially, the decision to perform cystectomy or oophorectomy depends on the clinical circumstances (see Chap. 9, Cystectomy Versus Oophorectomy). Regardless, the entire adnexa should be removed once a malignant ovarian germ cell tumor is diagnosed. A generalist in obstetrics and gynecology should request intraoperative assistance with staging from a gynecologic oncologist or refer the patient postoperatively if a specialist is not immediately available. At a minimum, the abdomen should be explored. Palpation of the omentum and upper abdomen and inspection of the pelvisâ€”especially the contralateral ovaryâ€”are easy to perform and document.

Pathology

CLASSIFICATION

The modified World Health Organization (WHO) classification of ovarian germ cell tumors is presented in Table 36-2 (Nogales,

2003). These tumors are composed of several histologically different tumor types derived from primordial germ cells of the embryonic gonad. There are two major categories: primitive malignant germ cell tumors (dysgerminomas) and teratomasâ€”almost all of which are accounted for by mature cystic teratomas (dermoid cysts).

Table 36-2 Modified World Health Organization Classification of Ovarian Germ Cell Tumors
Primitive germ cell tumors
Dysgerminoma
Yolk sac tumor (endodermal sinus tumor)
Embryonal carcinoma
Polyembryoma
Nongestational choriocarcinoma
Teratomas
Immature
Mature
Solid
Cystic (dermoid cyst)
Monodermal and highly specialized
Thyroid tumors (struma ovarii: benign or malignant)
Carcinoids
Neuroectodermal tumors
Carcinomas (squamous cell or adeno-)
Melanocytic group
Sarcomas
Sebaceous tumors
Mixed forms (tumors composed of two or more of the above pure types)

HISTOGENESIS

Primitive germ cells migrate from the wall of the yolk sac to the gonadal ridge. As a result, most germ cell tumors arise in the gonad. Rarely, these tumors may develop primarily in extragonadal sites such as the central nervous system, mediastinum, or retroperitoneum (Hsu, 2002).

Ovarian germ cell tumors have a variable pattern of differentiation (Fig. 36-3). Dysgerminomas are primitive neoplasms that do not have the potential for further differentiation. Embryonal carcinomas are composed of multipotential cells that are capable of further differentiation. This lesion is the precursor of several other types of extraembryonic (yolk sac tumor, choriocarcinoma) or

embryonic (teratoma) germ cell tumors. The process of differentiation is dynamic, and the resulting neoplasms may be composed of different elements showing various stages of development (Teilum, 1965).

FIGURE 36-3

Differentiation pathway of germ cell tumors.

Dysgerminoma

RISK FACTORS

Half of all malignant ovarian germ cell tumors are dysgerminomas. These tumors are the most common ovarian malignancy detected during pregnancy. This is believed to be an age-related coincidence, however, and not due to some particular characteristic of gestation.

Five percent of dysgerminomas are discovered in phenotypic females with karyotypically abnormal gonads, specifically, with the presence of a normal or abnormal Y chromosome (Morimura, 1998). Commonly, this group includes those with Turner syndrome mosaicism (45,X/46,XY), Klinefelter syndrome (46,XY, male pseudohermaphroditism), and Swyer syndrome (46,XY, puregonadal dysgenesis) (see Chap. 18, Male Pseudohermaphroditism (Category II)). The dysgenetic gonads of these individuals often contain gonadoblastomas, which are benign germ cell neoplasms. These tumors may regress or alternatively may undergo malignant transformation, most commonly to dysgerminoma. Because approximately 40 percent of gonadoblastomas in these individuals undergo malignant transformation, both ovaries should be removed (Hoepffner, 2005; Pena-Alonso, 2005).

CLINICAL FINDINGS

Dysgerminomas are the only germ cell malignancy with a significant rate of bilateral ovarian involvementâ€”15 to 20 percent. Half of patients with bilateral lesions will have grossly obvious disease, whereas cancer in the remainder will be detected only microscopically. Five percent of women have elevated serum hCG levels due to intermingled syncytiotrophoblasts. Similarly, serum lactate dehydrogenase (LDH) and the isoenzymes LDH-1 and LDH-2 also may be useful in monitoring individuals for disease recurrence (Pressley, 1992; Schwartz, 1988).

Dysgerminomas have a variable gross appearance but in general are solid, pink to tan to cream-colored, lobulated masses. Microscopically, there is a monotonous proliferation of large, rounded, polyhedral clear cells that are rich in cytoplasmic glycogen and contain uniform central nuclei with one or a few prominent nucleoli. The tumor cells resemble closely the primordial germ cells

of the embryo and are identical histologically to seminoma of the testis.

TREATMENT

Treatment of dysgerminoma involves fertility-sparing surgery with unilateral salpingo-oophorectomy (USO) and careful surgical staging of disease (Ayhan, 2000). Preservation of the contralateral ovary, however, leads to "recurrent" dysgerminoma in 5 to 10 percent of retained gonads over the next 2 years. This finding in many cases is thought to reflect the high rate of clinically occult disease in the remaining ovary rather than true recurrence. Indeed, 75 percent of recurrences develop within the first year of diagnosis. Other common recurrence sites are within the peritoneal cavity or retroperitoneal lymph nodes. Despite this significant incidence of recurrent disease, a conservative surgical approach does not adversely affect long-term survival because of this cancer's sensitivity to chemotherapy.

Dysgerminomas have the best prognosis of all malignant ovarian germ cell tumor variants (Lai, 2005; Yilmaz, 2003). Three quarters are stage I at diagnosis, and the 5-year survival exceeds 95 percent (Table 36-3). Even those with advanced disease have high survival rates following chemotherapy. For example, those with stage IIâ€“IV disease have an 85 to 90 percent survival rate with platinum-based agents. However, advanced stage remains the most important prognostic factor (Ayhan, 2000; Lai, 2005).

Table 36-3 Stage and Survival of Common Malignant Ovarian Germ Cell Tumors

	Dysgerminoma	**Yolk Sac Tumor**	**Immature Teratoma**
Stage at diagnosis			
I	75%	67%	50â€“60%
IIâ€“IV	25%	33%	40â€“50%
Five-year survival			
Stage I	>95%	80%	90â€“95%
Stage IIâ€“IV	85â€“90%	<10%	75â€“80%

Sources for survival figures are referenced within the text.

Yolk Sac Tumors

CLINICAL FINDINGS

Yolk sac tumors account for 20 percent of all malignant ovarian germ cell tumors. These lesions previously were called *endodermal sinus tumors,* but the terminology has been revised recently. A third of patients are premenarchal at the time of initial presentation. Involvement of both gonads is rare, and the other ovary usually is involved with metastatic disease only when there are other metastases in the peritoneal cavity.

Grossly, these tumors form solid masses that are more yellow and friable than dysgerminomas. They are often focally necrotic and hemorrhagic, with cystic degeneration and rupture. The microscopic appearance of yolk sac tumors is often diverse. The most common appearance, the reticular pattern, reflects extraembryonic differentiation, with formation of a network of irregular, anastomosing spaces that are lined by primitive epithelial cells. *Schiller-Duval bodies* are pathognomonic when present. These characteristically have a single papilla that is lined by tumor cells and contains a central vessel. Alpha-fetoprotein is commonly produced by these tumors. As a result, yolk sac tumors usually contain cells that stain immunohistochemically for AFP, and serum levels can serve as a reliable tumor marker in posttreatment surveillance.

TREATMENT

Yolk sac tumors are the most deadly malignant ovarian germ cell tumor type. All patients are treated with chemotherapyâ€”regardless of stage. Two thirds present with stage I disease and have a 5-year survival of 80 percent.

Unfortunately, yolk sac tumors have a propensity for rapid growth, peritoneal spread, and distant hematogenous dissemination to the lungs. Accordingly, individuals with stage IIâ€“IV disease have a dismal survival rate of less than 10 percent. Patients die within 2 years of diagnosis in greater than 90 percent of these more advanced cases (Ayhan, 2005; Fujita, 1993). Poor prognostic factors include an advanced initial cancer stage, residual disease following surgical staging, and ascites (Nawa, 2001).

Other Primitive Germ Cell Tumors

The rarest subtypes of nondysgerminomatous tumors typically are mixed with other more common variants and usually are not found in pure form.

EMBRYONAL CARCINOMA

Patients diagnosed with embryonal carcinoma characteristically are younger, with a mean age of 14 years, than those having other types of germ cell tumors. Epithelial cells resembling those of the embryonic disk comprise these primitive tumors. The solid disorganized sheets of large anaplastic cells, gland-like spaces, and papillary structures are distinctive and allow easy identification of these tumors (Ulbright, 2005). Although dysgerminomas are the most common germ cell tumor resulting from malignant transformation of gonadoblastomas in women with dysgenetic gonads, occasionally embryonal "testicular" tumors also may originate (LaPolla, 1990). Embryonal carcinomas typically produce hCG, and 75 percent also secrete AFP.

POLYEMBRYOMA

Polyembryomas characteristically contain many embryo-like bodies, each with a small central "germ disk" positioned between two cavities, one mimicking an amnionic cavity and the other a yolk sac. Syncytiotrophoblast giant cells are frequent, but elements other than the embryoid bodies should constitute less than 10 percent of the tumor for the *polyembryoma* designation to be used. Conceptually, these tumors may be viewed as a bridge between the primitive (dygerminoma) and differentiated (teratoma) germ cell tumor types. For this reason, polyembryomas often are considered to be the most immature of all teratomas (Ulbright, 2005). Serum AFP or hCG levels or both may be elevated in these individuals due to the yolk sac and syncytial components (Takemori, 1998).

CHORIOCARCINOMA

Primary ovarian choriocarcinoma arising from a germ cell appears similar to gestational choriocarcinoma with ovarian metastases. The distinction is important because nongestational tumors have a poorer prognosis (Corakci, 2005). The detection of other germ cell components indicates nongestational choriocarcinoma, whereas a concomitant or proximate pregnancy suggests a gestational form (Ulbright, 2005). Clinical manifestations are common and result from the high hCG levels produced by these tumors. These elevated levels may induce sexual precocity in prepubertal girls or menometrorrhagia in reproductive-aged women (Oliva, 1993).

MIXED GERM CELL TUMORS

Ovarian germ cell tumors have a mixed pattern of cellular differentiation in 10 percent of patients. Dysgerminoma is the most common component and typically is seen with yolk sac tumor or immature teratoma or both. The frequency of bilateral ovarian involvement depends on the presence or absence of a dysgerminoma component and increases when present. However, treatment and prognosis are determined by the nondysgerminomatous component (Low, 2000). For this reason, elevated serum hCG and particularly AFP levels in a woman with a presumed pure dysgerminoma should prompt a search for other germ cell components by more extensive histologic evaluation (Aoki, 2003).

Immature Teratomas

CLINICAL FINDINGS

Immature teratomas account for 20 percent of all malignant ovarian germ cell tumors and approximate the frequency of yolk sac tumors. They are composed of tissues derived from the three germ layers: ectoderm, mesoderm, and endoderm. The presence of immature or embryonal structures, however, distinguishes these tumors from the much more common and benign mature cystic teratoma (dermoid cyst). Bilateral ovarian involvement is rare, but 10 percent of patients have a mature teratoma in the contralateral ovary. Tumor markers often are negative unless the immature teratoma is comingled with other germ cell tumor types. Of these, AFP, cancer antigen 125 (CA125), CA-19-9, and carcinoembryonic antigen (CEA) may be helpful in some cases (Li,

2002).

On gross external inspection, these tumors appear as large, rounded or lobulated, soft or firm masses. They frequently perforate the ovarian capsule and invade locally. The most frequent site of dissemination is the peritoneum and much less commonly the retroperitoneal lymph nodes. With local invasion, surrounding adhesions commonly form and are thought to explain the lower rates of torsion with this tumor compared with that of its benign mature counterpart (Cass, 2001). On cut surface, the interior typically is solid with intermittent cystic areas, but occasionally the reverse is seen, with solid nodules present only in the cyst wall. Solid parts may correspond to the immature elements, cartilage, bone, or a combination of these, whereas cystic areas are filled with serous or mucinous fluid or sebaceous material and hair.

Microscopic examination reveals a disorderly mixture of tissues. Of the immature elements, neuroectodermal tissues almost always predominate and are arranged as primitive tubules and sheets of small, round, malignant cells that may be associated with glia formation. The diagnosis typically is difficult to confirm at frozen section evaluation, and most tumors will be confirmed only on final pathologic review. Tumors are graded 1 to 3 primarily by the amount of immature neural tissue they contain. O'Connor and Norris (1994) analyzed 244 immature teratomas and noted significant inconsistencies in grade assignment by different observers. For this reason, they proposed changing the system to two grades: low (previously grades 1 and 2) and high (previously grade 3). This practice, however, has not been universally accepted.

TREATMENT AND PROGNOSIS

In general, survival is predicted most accurately by the histologic grade of the tumor. For example, two thirds of immature teratomas are stage I at diagnosis and have a 5-year survival rate of 90 to 95 percent (Gershenson, 1986b; O'Connor, 1994). Those with stage IA, grade 1 immature teratomas have an excellent prognosis and do not require adjuvant chemotherapy (Bonazzi, 1994; Marina, 1999). Patients with stage IIâ€"IV disease have a 70 to 80 percent 5-year survival rate (Bonazzi, 1994; Kojs, 1997; Williams, 1994a).

Unilateral salpingo-oophorectomy (USO) is the standard care for these and other malignant germ cell tumors in reproductive-aged women. Beiner and colleagues (2004), however, treated eight women with early-stage immature teratoma with ovarian cystectomy and adjuvant chemotherapy and noted no recurrences.

Immature teratomas may be associated with mature tissue implants studding the peritoneum that do not increase the stage of the tumor or diminish the prospect of survival. However, these implants of mature teratomatous elements, even though benign, are resistant to chemotherapy and can enlarge during or after chemotherapy. Termed the *growing teratoma syndrome,* these implants require second-look surgery and resection to exclude recurrent malignancy (Geisler, 1994; Umekawa, 2005).

MALIGNANT TRANSFORMATION OF MATURE CYSTIC TERATOMAS (DERMOID CYSTS)

These rare tumors are the only germ cell variants that typically develop in postmenopausal women. Malignant areas usually are found as small nodules in the cyst wall or a polypoid mass within the lumen after removal of the entire mature cystic teratoma (Pins, 1996). Squamous cell carcinoma is most common and is found in approximately 1 percent of mature cystic teratomas. Other malignant tumors identified include basal cell carcinomas, sebaceous tumors, malignant melanomas, adenocarcinomas, sarcomas, and neuroectodermal tumors. Moreover, endocrine-type neoplasms such as struma ovarii (teratoma composed mainly of thyroid tissue) and carcinoid may be found within mature cystic teratomas. These are malignant in less than 5 percent of patients. The malignant struma rarely functions at a clinically relevant level, but the carcinoid tumor does in a third of patients (Robboy, 1980; Young, 1993).

Treatment

SURGERY

A vertical abdominal incision traditionally is recommended if ovarian malignancy is suspected. However, investigators with advanced endoscopic skills have noted laparoscopy to be a safe and effective alternative for those women with small ovarian masses and apparent stage I disease (Chi, 2005). If present, ascites is evacuated and sent for cytologic evaluation. Otherwise, washings of the pelvis and paracolic gutters are collected for analysis prior to manipulation of intraperitoneal contents. Washings can be discarded later if intraoperative evaluation or frozen-section interpretation is unequivocally benign. Regardless of the

surgical approach, the entire peritoneal cavity should be systematically inspected. The ovaries should be assessed for size, tumor involvement, capsular rupture, external excrescences, and adherence to surrounding structures.

Fertility-sparing USO should be performed in all reproductive-aged women diagnosed with malignant ovarian germ cell tumors because this conservative approach in general does not adversely affect survival (Peccatori, 1995). Following USO, blind biopsy or wedge resection of a normal-appearing contralateral ovary is not recommended. For those who have completed childbearing, hysterectomy with bilateral salpingo-oophorectomy (BSO) is appropriate. In either case, following removal of the affected ovary, surgical staging by laparotomy or laparoscopy proceeds as previously described for epithelial ovarian cancer (see Chap. 35, Surgical Staging). Because of tumor dissemination patterns, lymphadenectomy is most important for dysgerminomas, whereas staging peritoneal and omental biopsies are particularly valuable for yolk sac tumors and immature teratomas (Gershenson, 1983).

Cytoreductive surgery generally is recommended for malignant ovarian germ cell tumors when extensive disease is encountered at initial surgery. Tumor debulking to a level of minimal residual disease improves the likelihood of response to chemotherapy and cure (Bafna, 2001; Nawa, 2001; Suita, 2002). The same general principles of cytoreductive surgery are applied as described for epithelial ovarian cancer (see Chap. 35, Primary Cytoreductive Surgery). Thus, minimal residual disease is considered to be that in which each remaining tumor implant measures less than 1 cm. Because of the exquisite chemosensitivity of most malignant germ cell tumors, however, surgeons may choose to be less aggressive in performing radical debulking procedures.

Many women will be referred to a gynecologic oncologist after USO with a tumor that was clinically confined to the excised ovary. For such patients, if initial surgical staging was incomplete, options may include a second surgery for primary staging, regular surveillance, or adjuvant chemotherapy. Because of its minimally invasive qualities, laparoscopy is a particularly attractive option for delayed surgical staging following primary excision and has been shown to accurately detect those women who need chemotherapy (Leblanc, 2004). Surgical staging following primary excision, however, is less important for scenarios in which chemotherapy will be administered regardless of surgical findings, such as clinical stage I yolk sac tumors and high-grade clinical stage I immature teratomas (Stier, 1996).

SURVEILLANCE

Patients with malignant ovarian germ cell tumors should be followed by careful clinical, radiologic, and serologic surveillance every 3 months for the first 2 years after completion of therapy (Dark, 1997). Ninety percent of recurrences develop within this time frame (Messing, 1992). Second-look surgery at the completion of therapy is not necessary in women with completely resected disease or in those individuals with advanced tumor that does not contain teratoma (Chambers, 1988; Gershenson, 1986a). However, incompletely resected immature teratoma is the one circumstance among all types of ovarian cancer in which patients clearly benefit from second-look surgery and excision of chemorefractory tumor (Culine, 1996; Rezk, 2005; Williams, 1994b).

CHEMOTHERAPY

Stage IA dysgerminomas and stage IA, grade 1 immature teratomas do not require additional chemotherapy. More advanced disease and all other histologic types of malignant ovarian germ cell tumors, however, are treated with combination platinum-based chemotherapy (Suita, 2002; Tewari, 2000). Successful management without postoperative chemotherapy has been reported, but adjuvant treatment generally is recommended (Chapman, 1994).

The standard regimen is a 5-day course of bleomycin, etoposide, and cisplatin (BEP) (Gershenson, 1990; Williams, 1987). Modified 2- or 3-day BEP combinations also have been shown recently to be safe and effective in pilot studies but are not used routinely in practice (Dimopoulos, 2004; Tay, 2000). For women with accurate staging and completely resected ovarian germ cell tumors, three courses of BEP will prevent recurrence in nearly all (Williams, 1994a). Carboplatin and etoposide, given in three cycles, has shown promise as an alternative for selected patients, but it warrants further study before it can be considered standard treatment (Williams, 2004). For women with incompletely resected disease, at least four courses of BEP are recommended currently (Williams, 1991).

Although no randomized clinical trials exist, the BEP regimen is considered the standard for patients with malignant ovarian germ cell tumors (Culine, 2000; Gershenson, 1990). This regimen is as effective but less toxic than a combination of cisplatin, vinblastine, and bleomycin (PVB) (Williams, 1987). Vincristine, dactinomycin, and cyclophosphamide (VAC) was another frequently

used regimen in the 1970s and 1980s, but it also has been supplanted by BEP because its sustained remission rate for advanced disease was disappointingly low (Gershenson, 1985; Wong, 1989). Because chemotherapy remains effective when used at the time of relapse, some investigators are attempting to identify additional low-risk, early-stage subgroups that may be observed postoperatively and thereby avoid treatment-related toxicity (Bonazzi, 1994; Cushing, 1999; Dark, 1997). However, before this strategy can be incorporated into general practice, additional large studies are necessary to determine relapse rates, salvage rates, and long-term survival rates in early-stage ovarian germ cell tumors managed without adjuvant chemotherapy.

RADIATION

Chemotherapy has replaced radiation as the preferred adjuvant treatment for all types of malignant ovarian germ cell tumors. This transition was prompted primarily by the marked sensitivity of these tumors to either modality but the higher likelihood of retained ovarian function using chemotherapy (Mitchell, 1991). Occasional situations still may exist in which radiotherapy should be considered. However, the main role currently is palliation of a germ cell tumor that has demonstrated resistance to chemotherapy.

RELAPSE

At least four courses of BEP chemotherapy is the preferred treatment for recurrent ovarian germ cell tumors in women managed initially with surgery alone. Patients who achieved a sustained clinical remission of greater than 6 months after completing BEP or another platinum-based chemotherapy regimen may be treated again with BEP. Because their tumors generally are more responsive, these platinum-sensitive patients have a much better prognosis. However, women who do not achieve remission with BEP chemotherapy or relapse within a few months (<6) are considered platinum resistant. For these individuals, treatment options are limited. One option for this group is VAC (Gershenson, 1985). Other potentially active drugs include paclitaxel, gemcitabine, and oxaliplatin (Hinton, 2002; Kollmannsberger, 2006).

Second-look procedures with surgical debulking have a limited role because of the inherent chemosensitivity of these recurrent tumors. Chemorefractory immature teratomas are notable exceptions (Munkarah, 1994). Growth or persistence of a tumor after chemotherapy does not necessarily imply progression of malignancy, but these masses still should be resected (Geisler, 1994).

Prognosis

Malignant ovarian germ cell tumors have an excellent prognosis when managed appropriately (see Table 36-3) (Lai, 2005). Histologic cell type, surgical stage, and the amount of residual disease at initial surgery are the major variables affecting prognosis. However, of the germ cell tumor group, dysgerminomas have a better prognosis overall than the nondysgerminomatous types (Yilmaz, 2003).

Most women treated with fertility-sparing surgery, with or without chemotherapy, will resume normal menses and are able to conceive and bear children (Curtin, 1994; Mitchell, 1999). In addition, none of the reported studies has noted an increased rate of birth defects or spontaneous abortion in those treated with chemotherapy (Brewer, 1999; Low, 2000; Tangir, 2003; Zanetta, 2001).

Management during Pregnancy

Persistent adnexal masses are detected in 1 to 2 percent of all pregnancies. These neoplasms usually are seen during routine obstetric sonographic examination, but occasionally a dramatically elevated maternal serum AFP (MSAFP) level is the presenting sign of a malignant germ cell tumor (Horbelt, 1994; Montz, 1989). Mature cystic teratomas (dermoid cysts) comprise a third of tumors resected during pregnancy. In contrast, dysgerminomas account for only 1 to 2 percent of such neoplasms but still are the most common ovarian malignancy during pregnancy. Development of other germ cell tumors is rare (Shimizu, 2003).

Initial surgical management including surgical staging is the same as for the nonpregnant woman (Horbelt, 1994; Zhao, 2006). Fortunately, very few patients have advanced disease necessitating radical dissection for cytoreduction. The decision to administer chemotherapy during pregnancy is controversial. Malignant ovarian germ cell tumors have the propensity to grow rapidly, and delaying treatment until after delivery is potentially hazardous. Treatment with BEP appears to be safe during pregnancy, but some reports have speculated that fetal complications are possible (Elit, 1999; Horbelt, 1994). For this reason, some advocate postponing treatment until the puerperium (Shimizu, 2003). Unfortunately, there are no results from large studies to resolve this dilemma. At our institution, we delay BEP administration until the puerperium for completely resected dysgerminomas.

Nondysgerminomatous tumors (mainly yolk sac tumors and immature teratomas) and incompletely resected disease, however, warrant strong consideration of chemotherapy during pregnancy.

OVARIAN SEX CORDÂ€"STROMAL TUMORS

Sex cordâ€"stromal tumors (SCSTs) are a heterogeneous group of rare neoplasms that originate from the ovarian matrix. Cells within this matrix have the potential for hormone production, and nearly 90 percent of hormone-producing ovarian tumors are SCSTs. As a result, individuals with these tumors typically present with signs and symptoms of estrogen or androgen excess.

Surgical resection is the primary treatment, and SCSTs generally are confined to one ovary at the time of diagnosis. Moreover, most have an indolent growth pattern and low malignant potential. For these reasons, few patients ever require platinum-based chemotherapy. Although recurrent disease often responds poorly to treatment, patients may live for many years because of characteristically slow tumor progression.

The overall prognosis of ovarian SCSTs is excellentâ€"primarily due to early-stage disease at diagnosis and curative surgery. The scarcity of these tumors, however, limits the understanding of their natural history, treatment, and prognosis.

Epidemiology

SCSTs account for significantly fewer than 5 percent of ovarian malignancies and are the least common major subtype of ovarian cancer. The age-adjusted incidence rate is much lower (0.20 per 100,000 women) than that for epithelial ovarian carcinomas (15.48) and half of that for malignant germ cell tumors (0.41). These tumors are more than twice as likely to develop in black women for reasons that are unclear (Quirk, 2005).

In contrast with epithelial ovarian cancers or malignant germ cell tumors, ovarian SCSTs typically affect women of all ages. This range contains a unique bimodal distribution that reflects inherent tumor heterogeneity. For example, juvenile granulosa cell tumors, Sertoli-Leydig cell tumors, and sclerosing stromal tumors are found predominantly in prepubertal girls and women within the first three decades of life (Schneider, 2005). Adult granulosa cell tumors commonly develop in older women, with a peak incidence between 50 and 55 years (Miller, 1997).

The etiology of SCSTs is unknown, and there are no proven risk factors. Several reports in the past few of decades, however, have suggested an association with these tumors and use of combination oral contraceptive pills or ovulation-induction drugs (Willemsen, 1993; Centers for Disease Control and Prevention, 1987). These observations prompted concern that exposure of the gonad to persistently high levels of pituitary gonadotropins aid malignant transformation. More recently, however, this has been disputed by investigators who demonstrated a 40-percent decline in the incidence of SCSTs since the 1960s despite dramatic increases in the use of these drugs (Unkila-Kallio, 1998).

There is no known inherited predisposition for the development of these tumors, and familial cases are rare. However, ovarian SCSTs do develop in association with several defined hereditary disorders at a frequency that exceeds mere chance. Associated disorders include Ollier disease, which is characterized by multiple benign but disfiguring cartiliaginous neoplasms, and Peutz-Jeghers syndrome, which is characterized by intestinal hamartomatous polyps (Stevens, 2005).

Diagnosis

SIGNS AND SYMPTOMS

Isosexual pseudopuberty is the presenting sign in more than 80 precent of prepubertal girls ultimately diagnosed with an ovarian SCST (Kalfa, 2005). Adolescents often report secondary amenorrhea. As a result, these young individuals presenting with endocrinologic symptoms tend to be diagnosed at earlier stages. Abdominal pain and distention are other common complaints in this age group (Schneider, 2003a).

In adult women, menometrorrhagia and postmenopausal bleeding are the most common symptoms. In addition, mild hirsutism that rapidly progresses to frank virilization should prompt evaluation to exclude these tumors. The classic presentation is a postmenopausal woman with rapidly evolving stigmata of androgen excess and with a complex adnexal mass. Abdominal pain and a mass palpable by the patient herself are other telling signs and symptoms (Chan, 2005; Miller, 1997).

PHYSICAL EXAMINATION

The size of SCSTs is widely variable, but most women have a palpable abdominal or pelvic mass on examinationâ€"regardless of their age. A fluid wave and other physical findings suggestive of advanced disease, however, are rare.

LABORATORY TESTING

Elevated circulating levels of testosterone or androstendione or both are strongly suggestive of an ovarian SCST in a woman with signs and symptoms of virilization. Clinical hyperandrogenism is more likely to be polycystic ovarian syndrome or idiopathic, but serum testosterone levels greater than 200 g/dL or dehydroepiandrosterone sulfate (DHEAS) levels greater than 8,000 µg/L should strongly suggest the possibility of an androgen-secreting tumor (see Chap. 17, Dehydroepiandrosterone Sulfate) (Carmina, 2006). In most instances, tumor marker studies are not obtained preoperatively because the diagnosis of ovarian SCST often is not suspected. When the diagnosis is confirmed, the appropriate tumor markers may be determined during or following surgery (Table 36-4).

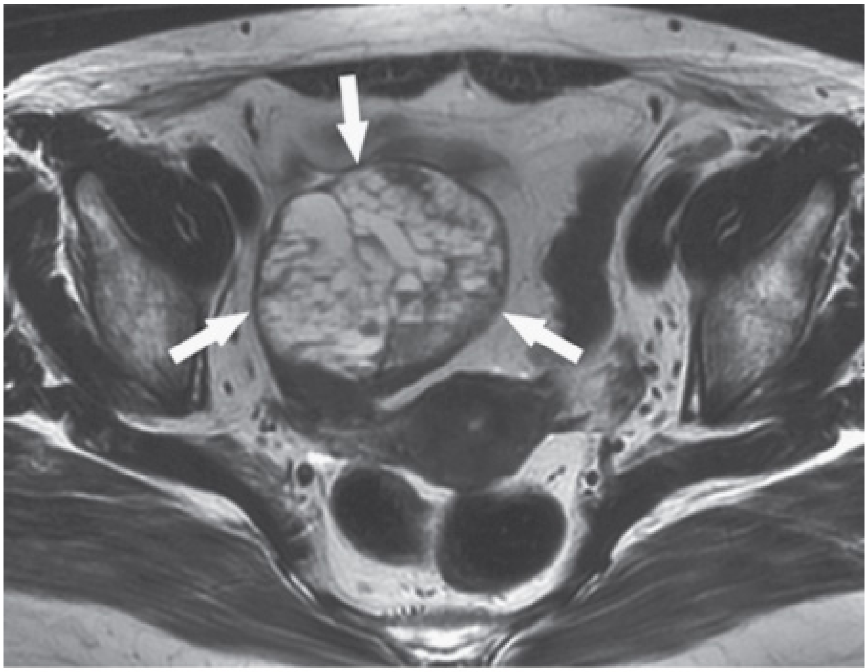
Table 36-4 Tumor Markers for Ovarian Sex Cord-Stromal Tumors with Malignant Potential

Granulosa cell tumors (adult and juvenile)	Inhibin A and B, estradiol (not as reliable)
Sertoliâ€"Leydig cell tumors	Inhibin A and B, alpha-fetoprotein (occasionally)
Sex cord tumor with annular tubules	Inhibin A and B
Steroid cell tumors not otherwise specified	Steroid hormones elevated pretreatment

IMAGING

The gross appearances of SCSTs range from large multicystic masses to small solid massesâ€"effectively precluding a specific radiologic diagnosis. Granulosa cell tumors often demonstrate semisolid features sonographically but are not reliably discernible from epithelial tumors (Sharony, 2001). In addition, the endometrium may be thickened from increased tumor estrogen production. Although CT scanning or MR imaging has been used to clarify indeterminant sonograms, there is no definitive radiologic study to diagnose these tumors (Fig. 36-4) (Jung, 2005).

FIGURE 36-4



Computed tomographic (CT) scan of a granulosa cell tumor. *(From Jung, 2005, with permission.)*

DIAGNOSTIC PROCEDURES

Patients with an ovarian mass suspicious for malignancy based on clinical and sonographic findings require surgical resection for definitive tissue diagnosis, staging, and treatment. Sonographically or CT-guided percutaneous biopsy has no role. Moreover, diagnostic laparoscopy or laparotomy with visual assessment of the adnexal mass alone is inadequate. Therefore, excision and pathologic evaluation are necessary.

Following removal, ovarian SCSTs usually can be distinguished histologically from germ cell tumors, epithelial ovarian cancers, or other spindle cell neoplasms by immunostaining for inhibin (Cathro, 2005; Schneider, 2005).

Role of the Generalist

Preoperatively, patients with a potentially malignant ovarian SCST should be referred to a gynecologic oncologist for evaluation. Most ovarian SCSTs, however, are diagnosed by generalists in obstetrics and gynecology following resection of a seemingly benign but complex mass in a woman with a CA125 level that is typically normal, if known beforehand. The initial surgery often is performed in a community-based hospital and without adequate staging. In this setting, prior to referral, histologic results should be reviewed and confirmed by an experienced pathologist. Following referral to a gynecologic oncologist, surgical staging via laparotomy or laparoscopy may be indicated.

Pathology

CLASSIFICATION

Ovarian SCSTs arise from sex cord and mesenchymal cells of the embryonic gonad (see Chap. 18, Gonadal Differentiation). Granulosa and Sertoli cells develop from the sex cords and thus from the coelomic epithelium. In contrast, theca cells, Leydig cells, and fibroblasts are derived from the mesenchyme (future stroma). This primitive gonadal stroma possesses sexual bipotentiality. Therefore, developing tumors may be composed of a male-directed cell type (Sertoli or Leydig cell) or a female-directed cell type (granulosa or theca cells). Although distinct categories of SCSTs have been defined, mixed tumors are relatively common (Table 36-5). For example, ovarian granulosa cell tumors may have admixed Sertoli components. Similarly, tumors that are

predominantly Sertoli or Sertoli-Leydig cells may contain minor granulosa elements. These mixed tumors are believed to arise from a common lineage with variable differentiation and do not represent two concurrent separate entities (McKenna, 2005; Vang, 2004).

HISTOLOGIC GRADING

Ovarian granulosa cell tumors are universally considered to have malignant potential, but most other SCST subtypes do not have definitive criteria for clearly defining benign and malignant. Attempts to grade these tumors using nuclear characteristics or mitotic activity counts have produced inconsistent results (Chen, 2003).

PATTERNS OF GROWTH AND SPREAD

The natural history of SCSTs in general differs greatly from that of epithelial ovarian carcinomas. For example, most of these tumors have low malignant potential. They are typically unilateral and remain localized, retain hormone-secreting functions, and infrequently relapse. Recurrences tend to be late and usually develop in the abdomen or pelvis. Bone metastases are extremely rare (Dubuc-Lissoir, 2001).

Granulosa Cell Tumors

Seventy percent of ovarian SCSTs are granulosa cell tumors. These tumors are formed by cells believed to arise from those surrounding the germinal cells within ovarian follicles. There are two clinically and histologically distinct types: the adult form, which comprises 95 percent of cases, and the juvenile type, comprising 5 percent.

ADULT GRANULOSA CELL TUMORS

Clinical Findings

Most women with an adult granulosa cell tumor are diagnosed after age 30, with the average age being 52 years. Menometrorrhagia and postmenopausal bleeding are common signs and reflect a prolonged exposure of the endometrium to estrogen (Miller, 1997). Related to this estrogen excess, coexisting pathologyâ€”such as endometrial hyperplasia or adenocarcinomaâ€”has been found in one quarter of patients with adult granulosa cell tumor. Similarly, breast enlargement and tenderness are common associated complaints, and secondary amenorrhea has been reported (Kurihara, 2004). Alternatively, symptoms may stem from the mass of the ovary rather than from hormones produced. An enlarging and potentially hemorrhagic tumor may cause abdominal pain and distention. Acute pelvic pain may suggest adnexal torsion, or tumor rupture with hemoperitoneum can mimic ectopic pregnancy.

During surgery, if an adult granulosa cell tumor is confirmed, tumor markers may be requested. Of these, inhibin A, inhibin B, and serum estradiol levels are most valuable. Inhibins have been demonstrated to be elevated months before clinical detection of disease and therefore, are considered more reliable for postoperative surveillance (Boggess, 1997; Lappohn, 1989). The diagnostic value of this marker, however, sometimes may be hampered by its physiologically broad normal range (Schneider, 2005). Estradiol has limited use in surveillance, particularly in a younger woman wishing to preserve fertility and having the contralateral ovary left in situ.

Grossly, adult granulosa cell tumors are large, multicystic, and often exceed 10 to 15 cm in diameter (Fig. 36-5). The surface is frequently edematous and unusually adherent to other pelvic organs. For this reason, more extensive dissection typically is required than for epithelial ovarian cancers or malignant germ cell tumors. During excision, inadvertent rupture and intraoperative bleeding from the tumor itself also are common.

Adult granulosa cell tumor. *(Courtesy of Dr. Raheela Ashfaq.)*

The interior of the tumor typically has a variable solid and cystic appearance with hemorrhagic areas. Microscopic examination shows predominately granulosa cells with pale, grooved, "coffee bean" nuclei. The characteristic microscopic feature is the *Call-Exner body* â€”a rosette arrangement of cells around an eosinophilic fluid space (Fig. 36-6).

Prognosis

Adult granulosa cell tumors are low-grade malignancies that typically demonstrate indolent growth. Ninety-five percent are unilateral, and 80 to 90 percent are stage I at diagnosis (Table 36-6). The 5-year survival for patients with stage I disease is 85 to

95 percent (Lauszus, 2001; Malmstrom, 1994; Miller, 1997). However, 15 to 25 percent of stage I tumors eventually will relapse. The median time to recurrence is 6 years but may be several decades (East, 2005). Fortunately, these indolent tumors usually progress slowly thereafter, and the median length of survival after relapse is another 6 years. Advanced tumor stage and residual disease are poor prognostic factors (Al Badawi, 2002; Sehouli, 2004). Stage IIâ€“IV tumors have a 5-year survival of 30 to 50 percent (Malmstrom, 1994; Miller, 1997; Piura, 1994). Cellular atypia and mitotic count may help in determining the prognosis but are difficult to quantify reproducibly (Miller, 2001).

Table 36-6 Stage and Survival of Common Ovarian Sex Cordâ€“Stromal Tumors

	Adult Granulosa Cell	**Sertoliâ€“Leydig Cell**
Stage at diagnosis		
I	80â€“90%	97%
IIâ€“IV	10â€“20%	2â€“3%
Five-year survival		
Stage I	85â€“95%	90â€“95%
Stage IIâ€“IV	30â€“50%	10â€“20%

Sources for survival figures are referenced within the text.

JUVENILE GRANULOSA CELL TUMORS

Clinical Findings

These rare neoplasms develop primarily in children and young adults, and half are diagnosed before puberty. The mean age at diagnosis is 13 years, but patients range from newborn to 67 years (Young, 1984). Juvenile granulosa cell tumors sometimes are associated with Ollier disease and Maffucci's syndrome (endochondromas and hemangiomas) (Young, 1984; Yuan, 2004).

In affected females, estrogen, progesterone, and testosterone levels may be elevated with suppression of gonadotropins. As a result, menstrual irregularities and amenorrhea are common. Prepubertal girls typically display isosexual peripheral precocious puberty, which is characterized by breast enlargement and development of pubic hair, vaginal secretions, and other secondary sexual characteristics (see Chap. 14, Precocious Puberty). These tumors infrequently secrete androgens, but in such cases, they may induce virilization. Despite these endocrinologic signs, a delayed diagnosis of juvenile granulosa cell tumors in pre- and postpubertal girls is common and associated with a high risk of peritoneal tumor spread (Kalfa, 2005).

In addition to hormonal effects, individuals may display tumor effects. For example, older patients usually seek medical attention for abdominal pain or swelling. Preoperative rupture with resulting hemoperitoneum may create acute abdominal symptoms in 5 percent of patients. Additionally, ascites is present in 10 percent (Young, 1984).

Juvenile granulosa cell tumors are grossly similar to the adult-type tumor with variable solid and cystic components. They can attain significant size, and the average diameter is 12 cm. Microscopically, cytologic features that distinguish these tumors from the adult type are their rounded, hyperchromatic nuclei without "coffee-bean" grooves. Call-Exner bodies are rare, but often there is a theca cell component (Young, 1984).

Prognosis

Prognosis is excellent, and the 5-year survival rate is 95 percent. Similar to adult-type tumors, 95 percent of juvenile granulosa cell tumors are unilateral and stage I at diagnosis (Young, 1984). However, the juvenile type is more aggressive in advanced stages, and the time to relapse and death is much shorter. Recurrences typically develop within 3 years. Later recurrences are unusual (Frausto, 2004).

Thecoma-Fibroma Group

THECOMAS

Thecomas are relatively common SCSTs that are unique because they typically develop in postmenopausal women in their mid-60s and develop infrequently before age 30. These solid tumors are among the most hormonally active of the SCSTs and usually produce excess estrogen. As a result, primary signs and symptoms are abnormal vaginal bleeding or pelvic mass or both. Many women also present with concurrent endometrial hyperplasia or adenocarcinoma (Aboud, 1997). These tumors are composed of lipid-laden stromal cells that are occasionally luteinized. Half these luteinized thecomas are either hormonally inactive or androgenic with the potential for inducing masculinization.

Thecomas are solid tumors that resemble the theca cells that normally surround the ovarian follicles (Chen, 2003). Because of this texture, these tumors appear sonographically as solid adnexal masses and may mimic extrauterine leiomyomas.

Bilateral ovarian involvement and extraovarian spread are rare. Fortunately, ovarian thecomas are clinically benign, and surgical resection is curative.

FIBROMAS/FIBROSARCOMAS

Fibromas are relatively common, hormonally inactive SCST variants. These solid, generally benign ovarian neoplasms arise from the spindled stromal cells that form collagen. Fibromas can produce ascites, resulting in a clinical picture (Meigs syndrome) suggestive of epithelial ovarian cancer (see Chap. 9, Other Clinical Manifestations). (Siddiqui, 1995). Ten percent will demonstrate increased cellularity and varying degrees of pleomorphorism and mitotic activity that indicate a tumor better characterized as having low malignant potential. Fibrosarcomas are rare, highly malignant tumors that have even more dramatic histologic features.

Sclerosing Stromal Tumors

These tumors are rare and account for less than 5 percent of SCSTs. The average patient age is 21 years, and 80 percent develop before age 30. Sclerosing stromal tumors are clinically benign and typically unilateral. Menstrual irregularities and pelvic pain are both common symptoms (Marelli, 1998). Ascites is seldom encountered (unlike fibromas), and sclerosing stromal tumors are hormonally inactive (unlike thecomas). Tumor size ranges from microscopic to 20 cm. Histologically, the presence of pseudolobulation of cellular areas separated by edematous connective tissue, increased vascularity, and prominent areas of sclerosis are distinguishing features.

Sertoliâ€“Stromal Cell Tumors

SERTOLI CELL TUMORS

Ovarian Sertoli cell tumors are rare and account for less than 5 percent of all SCSTs. The mean patient age at diagnosis is 30 years, but ages range from 2 to 76 years. One quarter of patients present with estrogenic or androgenic manifestations, but most tumors are clinically nonfunctional.

Sertoli cell tumors typically are unilateral, solid, yellow, and measure 4 to 12 cm. Derived from the cell type that gives rise to the seminiferous tubules, these tumor cells often organize into histologically characteristic tubules (Young, 2005). Sertoli cell tumors, however, also may mimic many different tumors, and immunostaining in these cases is invaluable to confirm the diagnosis.

More than 80 percent are stage I at diagnosis, and most are clinically benign. Moderate cytologic atypia, brisk mitotic activity, and tumor cell necrosis are indicators of greater malignant potential. These findings are found in 10 percent of individuals with stage I disease and in most of those with stage IIâ€“IV tumors. The risk of recurrence is higher when these features are identified (Oliva, 2005).

SERTOLI-LEYDIG CELL TUMORS

Sertoliâ€“Leydig cell tumors comprise only 5 to 10 percent of ovarian SCSTs. Their incidence mirrors that of Sertoli cell tumors, and the average age is 25 years. Although Sertoliâ€“Leydig cell tumors have been identified in children and postmenopausal females, more than 90 percent develop during the reproductive years.

These tumors frequently produce sex steroid hormones, most commonly androgens. As a result, frank virilization develops in a third of women, and another 10 percent have clinical manifestations of androgen excess characterized by hirsutism, temporal balding, deepening of the voice, and clitoral enlargement (Young, 1985). Menstrual disorders are also common. Accordingly, Sertoliâ€"Leydig cell tumors should be suspected preoperatively in a patient with a unilaterally palpable adnexal mass and androgenic manifestations. For these women, an elevated serum testosterone:androstenedione ratio further suggests the diagnosis.

Although these hormonal effects develop frequently, half of patients will have nonspecific abdominal mass symptoms as their only presenting complaint. Associated ascites is uncommon (Outwater, 2000). Thyroid abnormalities also coexist with Sertoliâ€"Leydig cell tumors at a frequency that exceeds mere chance.

These tumors tend to be large at the time of excision, with an average diameter of 13 cm, but ranges from 1 to 50 cm have been reported. In most cases, Sertoliâ€"Leydig cell tumors appear yellow and lobulated. Tumors can be solid, partially cystic, or completely cystic, and they may or may not have polypoid or vesicular structures in their interior. Microscopically, these morphologically diverse tumors contain cells resembling epithelial and stromal testicular cells in varying proportions. The five subtypes of differentiation (well, intermediate, poor, retiform, and heterologous) have considerable overlap. Well-differentiated tumors are all clinically benign (Chen, 2003; Young, 2005).

Overall, 15 to 20 percent of Sertoliâ€"Leydig cell tumors are clinically malignant. Prognosis depends predominantly on the stage and degree of tumor differentiation in these malignant variants. For example, Young and Scully (1985) performed a clinicopathological analysis of 207 patients and identified stage I disease in 97 percent. The 5-year survival for patients with stage I disease exceeds 90 percent (Zaloudek, 1984). Malignant features were observed in approximately 10 percent of tumors with intermediate differentiation and 60 percent of poorly differentiated tumors. Retiform and heterologous elements are seen only in intermediate or poorly differentiated Sertoliâ€"Leydig cell tumors and typically are associated with poorer prognosis. Overall, the 2 to 3 percent of patients with stage IIâ€"IV disease have a dismal prognosis (Young, 1985).

Sex Cord Tumors with Annular Tubules

Sex cord tumors with annular tubules account for 5 percent of SCSTs and are characterized by ring-shaped tubules and distinctive cellular elements that are histologically intermediate between Sertoli cell and granulosa cell tumors. There are two clinically distinct types. First, one third are clinically benign and develop in patients with Peutz-Jeghers syndrome (PJS). These tumors are typically small, multifocal, calcified, bilateral, and are diagnosed incidentally. Fifteen percent of PJS-associated patients also will develop adenoma malignum of the cervix, which is a rare and extremely well-differentiated adenocarcinoma. In contrast, two thirds of tumors are not associated with PJS. These tumors are usually larger, unilateral, symptomatic, and carry a clinical malignancy rate of 15 to 20 percent (Young, 1982).

Steroid Cell Tumors

Fewer than 5 percent of SCSTs are steroid cell tumors. The average age at diagnosis is the mid-20s, but patients can present at virtually any age. These tumors are composed entirely or predominantly of cells that resemble steroid hormoneâ€"secreting cells and are categorized according to the histologic composition of these cells. *Stromal luteomas* are clinically benign tumors that, by definition, lie completely within the ovarian stroma. They are usually seen in postmenopausal women. Estrogenic effects are common, but occasional individuals have androgenic manifestations. *Leydig cell tumors* are also benign and typically seen in postmenopausal women. They are distinguished microscopically by crystals of Reinke within the cytoplasm. Leydig cells secrete testosterone, and these tumors usually are associated with androgenic effects. *Steroid cell tumors not otherwise specified* (NOS) are the most common subtype within this group and typically present in younger reproductive-aged women. Some of these may represent large stromal luteomas that have grown to reach the ovarian surface or Leydig cell tumors in which Reinke crystals cannot be identified. These tumors typically are associated with androgenic excess, but estrogenic or cortisol overproduction (i.e., Cushing syndrome) also has been reported. A third of steroid cell tumors NOS are clinically malignant and have a dismal prognosis (Oliva, 2005).

Unclassified Sex Cordâ€"Stromal Tumors

Unclassified tumors account for 5 percent of SCSTs and have no clearly predominant pattern of testicular (Sertoli cells) or ovarian

(granulosa cells) differentiation. These ill-defined tumors are especially common during pregnancy owing to alterations in their usual clinical and pathologic features (Young, 2005). They may be estrogenic, androgenic, or nonfunctional. The prognosis is similar to that of granulosa cell tumors and Sertoliâ€"Leydig cell tumors of similar degrees of differentiation.

Gynandroblastomas

Gynandroblastomas are the rarest type of ovarian SCST. Women present at a mean age of 30 years and typically have menstrual irregularities or evidence of hormonal excess. The tumors are characterized by intermingled granulosa cells and tubules of Sertoli cells. Theca or Leydig cells or both also may be present in varying degrees. Gynandroblastomas have low malignant potential, and only one death has been reported (Martin-Jimenez, 1994).

Treatment

SURGERY

The mainstay of treatment for patients with an ovarian SCST is surgical resection. The goals of surgery are to establish a definitive tissue diagnosis, determine the extent of disease by appropriate ovarian cancer staging procedures, and remove all grossly visible disease (see Chap. 35, Surgical Approach to Cytoreductive Surgery). Staging laparotomy or laparoscopy is essential to determine the extent of disease and the need for adjuvant therapy in most individuals with potentially malignant SCST subtypes (Fig. 36-7) (Chan, 2005). Moreover, in planning surgery, clinicians should consider the patient's age and desire for future fertility. Hysterectomy with BSO is performed for those who have completed childbearing, whereas fertility-sparing USO with preservation of the uterus may be appropriate in the absence of obvious disease spread to these organs (Zanagnolo, 2004). Endometrial sampling should be performed especially when fertility-sparing surgery is planned in women with granulosa cell tumors or thecomas because many of these patients will have coexisting hyperplasia or adenocarcinoma that may affect the decision for hysterectomy.

Staging of sex cordâ€"stromal tumors. PJS = Peutz-Jeghers syndrome.

Minimally invasive laparoscopic surgery has a variety of relevant applications. For some, the diagnosis of SCST may not be discovered until the mass is removed laparoscopically and sent for frozen section evaluation. Laparoscopic surgical staging then can proceed. When the diagnosis is not made until the final pathology report is confirmed postoperatively, laparoscopic staging may be proposed to determine whether metastatic disease is present while reducing the morbidity of another operation (Kriplani, 2001).

Surgical removal of hormone-producing SCSTs results in an immediate drop in elevated preoperative sex steroid hormone levels. Physical manifestations of these elevated levels, however, resolve partially or completely more gradually.

SURVEILLANCE

In general, women with stage I ovarian SCSTs have an excellent prognosis following surgery alone and usually can be followed at regular intervals without the need for further treatment (Schneider, 2003a). Surveillance includes a general physical and pelvic examination, serum marker testing, and imaging tests as clinically indicated.

CHEMOTHERAPY

The decision to administer postoperative therapy depends on a variety of factors (Fig. 36-8). Although typically treated solely with surgery, malignant stage I ovarian SCSTs may require adjuvant chemotherapy when large tumor size, high mitotic index, capsular excrescences, tumor rupture, incomplete staging, or equivocal pathology results are noted. Women with one or more of these suspicious features are thought to be at higher risk of relapse and should be considered for platinum-based chemotherapy (Schneider, 2003b). In addition, stage IIâ€“IV disease warrants postoperative treatment. In general, SCSTs display less sensitivity to chemotherapy than other ovarian malignancies, but most women at high risk for disease progression can be treated successfully with adjuvant cisplatin-based chemotherapy (Schneider, 2005).

FIGURE 36-8

Postoperative treatment of sex cordâ€“stromal tumors.

The 5-day bleomycin, etoposide, and cisplatin (BEP) regimen is the most widely used first-line chemotherapy combination (Gershenson, 1996; Homesley, 1999). For those with completely resected disease, three courses given every 3 weeks are sufficient.

Four cycles are recommended for patients with incompletely resected tumor (Homesley, 1999). In addition to BEP, taxanes have demonstrated activity against ovarian SCSTs, and combination paclitaxel and carboplatin chemotherapy has shown promising results (Brown, 2004, 2005). Unfortunately, the relative rarity of women who have ovarian SCST and receive chemotherapy limits the ability to conduct randomized studies.

RADIATION

Postoperative radiation therapy currently has a limited role in the management of ovarian SCSTs. There is some evidence indicating a prolonged survival in at least some women with newly diagnosed disease who received whole abdominal radiotherapy (Wolf, 1999). However, chemotherapy is usually the primary postoperative treatment because it is generally better tolerated, more widely accessible, and easier to administer. Radiation is best reserved for palliation of local symptoms (Dubuc-Lissoir, 2001).

RELAPSE

The management of recurrent ovarian SCST depends on the clinical circumstances. Secondary surgical debulking should be strongly considered because of the indolent growth pattern, the typically long disease-free interval after initial treatment, and the inherent insensitivity to chemotherapy (Crew, 2005; Powell, 2001). Platinum-based combination chemotherapy is the primary treatment chosen for recurrent disease, with or without surgical debulking (Uygun, 2003). Of available regimens, BEP is administered most frequently because it has the highest known response rate (Homesley, 1999). Paclitaxel is another promising agent that is currently being evaluated in a phase II Gynecologic Oncology Group trial (protocol 187) and warrants further investigation when combined with platinum (Brown, 2005).

There is no standard treatment for women who have progressive disease despite aggressive surgery and platinum-based chemotherapy. The vincristine, actinomycin D, and cyclophosphamide (VAC) regimen has limited activity (Ayhan, 1996; Zanagnolo, 2004). However, hormone therapy may be useful and minimally toxic in women with chemoresistant tumors (Hardy, 2005). Medroxyprogresterone acetate and the GnRH agonist leuoprolide acetate each have demonstrated activity in halting the growth of recurrent ovarian SCSTs (Fishman, 1996; Homesley, 1999). GnRH antagonists, however, may not be as effective (Ameryckx, 2005). In addition to traditional drugs, novel agents have been synthesized that bind to specific ovarian SCST tumor receptors and lead to cell death. These are still under investigation in animal models and are not yet available clinically (Bodek, 2005).

Prognosis

In general, ovarian SCSTs portend a much better prognosis than epithelial ovarian carcinomas chiefly because most women with SCSTs are diagnosed with stage I disease. Stage IIâ€"IV tumors are rare, but women with these cancers have a poor prognosis similar to their epithelial counterparts. Of the clinical factors affecting prognosis, surgical stage is the most important (Zanagnolo, 2004). Chan and colleagues (2005) performed a multivariate analysis of 83 women with SCSTs and concluded that age younger than 40 years, smaller tumor size, and complete tumor removal also were independent predictors of improved survival.

Management during Pregnancy

Ovarian SCSTs are detected rarely during pregnancy (Okada, 2004). In a California population-based study of more than 4 million obstetric patients, one granulosa cell tumor was diagnosed among 202 women with an ovarian malignancy (Leiserowitz, 2006). Granulosa cell tumors are the most common SCST, but only 10 percent are diagnosed during pregnancy (Hasiakos, 2006). A third of pregnant women with SCSTs are diagnosed incidentally at cesarean delivery, a third have abdominal pain or swelling, and the remainder may present with hemoperitoneum, virilization, or vaginal bleeding (Young, 1984).

Surgical management should be the same as for the nonpregnant woman. For most, conservative management with USO and surgical staging is the primary procedure, but hysterectomy and BSO may be indicated in selected circumstances (Young, 1984). Postoperative chemotherapy typically is withheld at our institution until after delivery because SCSTs have an indolent growth pattern.

GESTATIONAL TROPHOBLASTIC DISEASE: INTRODUCTION

Gestational trophoblastic disease (GTD) refers to a spectrum of interrelated but histologically distinct tumors originating from the placenta (Table 37-1). These diseases are characterized by a reliable tumor marker (β-subunit of human chorionic gonadotropin [β-hCG]) and have varying tendencies toward local invasion and spread.

Table 37-1 Modified World Health Organization Classification of Gestational Trophoblastic Disease

Modified from le-Ming, 2002, with permission.

Gestational trophoblastic neoplasia (GTN) refers to the subset of gestational trophoblastic disease that develops malignant sequelae. These tumors require formal staging and typically respond favorably to chemotherapy. Most commonly, GTN develops after a molar pregnancy but may follow any gestation.

The prognosis for most cases of GTN is excellent, and patients are cured routinely even in the presence of widespread metastases. The outlook for preservation of fertility and for successful subsequent pregnancy outcomes is equally bright (Schorge, 2000). Accordingly, although gestational trophoblastic disease is uncommon, because the opportunity for cure is great, clinicians should be familiar with its presentation, diagnosis, and management.

EPIDEMIOLOGY AND RISK FACTORS

Incidence

The incidence of gestational trophoblastic disease has remained fairly constant at approximately 1 to 2 per 1,000 deliveries in the United States and Europe (Drake, 2006; Loukovaara, 2005; Smith, 2003). A similar frequency has been observed in South Africa and Turkey (Moodley, 2003; Ozalp, 2003). Although higher incidence rates have been reported in parts of Asia, this may have largely reflected discrepancies between population-based and hospital-based data collection. For example, a recent South Korean population-based study noted a drop in the incidence from 40 per 1,000 deliveries to 2 per 1,000 that was coincident with refinement in disease terminology and classification (Kim, 2004). Similarly, hospital-based studies in Japan and Singapore have shown a decreased incidence approaching that in the United States and Europe (Chong, 1999; Matsui, 2003). Some ethnic groups, however, appear to be at higher risk of developing gestational trophoblastic disease. Hispanics and Native Americans living in the United States reportedly have an increased incidence, as do certain population groups living in Southeast Asia (Drake, 2006; Smith, 2003; Tham 2003).

Maternal Age

Maternal age at the upper and lower extremes has been found to carry a higher risk of gestational trophoblastic disease (Loukovaara, 2005; Tham, 2003). More specifically, teenage women and those aged 36 to 40 years have approximately double the risk. Patients older than 40 years of age have a 7.5-fold higher risk, and the association is most pronounced among women at least 45 years of age (Parazzini, 1991; Sebire, 2002a). One explanation may relate to ova from older women having higher rates of abnormal fertilization (Schorge, 2000). Similarly, older paternal age also has been associated with increased risk (La Vecchia, 1984; Parazzini, 1986).

Obstetric History

In addition to age, a history of prior unsuccessful pregnancies increases the risk of gestational trophoblastic disease. For example, previous spontaneous abortion at least doubles the risk of molar pregnancy (Parazzini, 1991). Moreover, a personal history of gestational trophoblastic disease increases the risk of developing a molar gestation in a subsequent pregnancy by at least 10-fold (Parazzini, 1991; Sebire, 2003). The frequency in a subsequent conception is approximately 1 to 2 percent, and most cases mirror the same type of mole as the preceding pregnancy (Berkowitz, 1994). Furthermore, following two episodes of molar pregnancy, 23 percent of later conceptions result in another molar gestation (Berkowitz, 1998). For this reason, women with a prior history of gestational trophoblastic disease should undergo first-trimester sonographic examination in subsequent pregnancies. Familial molar pregnancies, however, are exceedingly rare (Fallahian, 2003).

Other Factors

In several case-control studies, combination oral contraceptive (COC) pill use has been associated with an increased risk of gestational trophoblastic disease. Specifically, prior COC pill use approximately doubles the risk, and a longer duration of use also seems to correlate positively with risk (Palmer, 1999; Parazzini, 2002). Moreover, women who used combination oral contraceptive pills during the cycle in which they became pregnant appear to have a fourfold higher risk (Palmer, 1999). Many of these associations, however, are weak and could be explained by confounding factors other than causality (Parazzini, 2002).

Certain epidemiologic characteristics appear to differ markedly between complete and partial moles. For example, vitamin A deficiency and low dietary intake of carotene are associated with an increased risk of only complete moles (Berkowitz, 1985, 1995; Parazzini, 1988a). Partial moles have been linked to higher educational levels, smoking, irregular menstrual cycles, and obstetric histories in which only male infants are among the prior live births (Berkowitz, 1995; Parazzini, 1986).

HYDATIDIFORM MOLE (MOLAR PREGNANCY)

Hydatidiform moles are abnormal pregnancies characterized histologically by aberrant changes within the placenta. Specifically, the chorionic villi in these placentas show varying degrees of trophoblastic proliferation and edema of the villous stroma. Based on the degree and extent of these tissue changes, hydatidiform moles are categorized as either *complete hydatidiform moles* or *partial hydatidiform moles* (Table 37-2). Cytogenetic studies have shown that chromosomal abnormalities play an integral role in the

development of hydatidiform moles (Lage, 1992). Overall survival from these potentially malignant conditions has been virtually 100 percent for the past few decades (Lurain, 1983).

Table 37-2 Features of Complete and Partial Hydatidiform Moles

Feature	Complete Mole	Partial Mole
Karyotype	46,XX or 46,XY	69,XXX or 69,XXY
Pathology		
Fetus/embryo	Absent	Present
Villous edema	Diffuse	Focal
Trophoblastic proliferation	Variable, may be marked	Focal and minimal
p57Kip2 immunostaining	Negative	Positive
Clinical presentation		
Typical Diagnosis	Molar gestation	Missed abortion
Postmolar malignant sequelae	15â€"20%	2â€"4%

Complete Hydatidiform Mole

KARYOTYPE AND HISTOLOGY

Classically, these molar pregnancies differ from partial moles with regard to their karyotype, their histologic appearance, and their clinical presentation. Complete moles typically have a complete diploid karyotype, and 85 percent of these are 46,XX. The chromosomes, however, in these pregnancies are entirely of paternal origin. In a process termed *androgenesis,* the ovum is fertilized by a haploid sperm, which then duplicates its own chromosomes after meiosis (Fig. 37-1) (Fan, 2002; Kajii, 1977). Although most of these moles are 46,XX, dispermic fertilization of a single ovum can produce a 46,XY karyotype (Lawler, 1987).

FIGURE 37-1

Pathogenesis of complete and partial moles. **A** . A 46,XX complete mole may be formed if a 23,X-bearing sperm penetrates a 23,X-containing egg whose genes have become "inactive". Paternal chromosomes then duplicate to create a 46,XX chromosomal complement solely of paternal origin. Alternatively, this same type of egg can be fertilized independently by two sperm, either 23,X- or 23,Y-bearing, to create a 46,XX or 46,XY chromosomal complement, again of paternal origin only. **B** . A partial mole may be formed if two sperm, either 23,X- or 23,Y-bearing, both fertilize a 23,X-containing egg. The resulting fertilized egg is triploid. Alternatively, a similar haploid egg may be fertilized by an unreduced diploid 46,XY sperm. (Redrawn from le-Ming, 2002.).

Microscopically, complete moles display enlarged, edematous villi and abnormal trophoblastic proliferation that diffusely involve the entire placenta (Fig. 37-2). Macroscopically, these changes transform the chorionic villi into clusters of vesicles with variable dimensions. Indeed, the name *hydatidiform mole* stems from this "bunch of grapes" appearance. In these pregnancies, no fetal tissue or amnion is produced. As a result, this mass of placental tissue completely fills the endometrial cavity (Fig. 37-3).

CLINICAL FINDINGS

The clinical presentation of a complete mole has changed considerably over the past few decades. More than half of patients diagnosed in the 1960s and 1970s had anemia and uterine sizes in excess of that predicted for their gestational age. In addition, hyperemesis gravidarum, preeclampsia, and theca-lutein cysts developed in approximately one quarter of women (Montz, 1988; Soto-Wright, 1995).

Complete moles, however, present infrequently today with these traditional signs and symptoms (Coukos, 1999). As a result of β-hCG testing and sonography, the mean gestational age at evacuation currently approximates 12 weeks, compared with 16 to 17 weeks in the 1960s and 1970s (Drake, 2006; Soto-Wright, 1995). Vaginal bleeding remains the most common symptom and still occurs in virtually all patients. One quarter of women will present with a uterine size greater than dates, but the incidence of anemia is less than 10 percent. Moreover, hyperemesis gravidarum, preeclampsia, and symptomatic theca-lutein cysts are observed rarely (Lazarus, 1999; Mosher, 1998; Soto-Wright, 1995). Currently, these sequelae typically occur chiefly in patients without early prenatal care who present with a more advanced gestational age and markedly elevated serum β-hCG levels (Osathanondh, 1986).

Plasma thyroxine levels are often elevated in women with complete moles, but clinical hyperthyroidism is unusual and is identified in only approximately 5 percent of patients (Amir, 1984; Berkowitz, 1987). In these circumstances, serum free thryoxine levels are elevated as a consequence of the thyrotropin-like effect of β-hCG (see Chap. 15, Peptide Hormones in Reproduction) (Hershman, 2004).

Partial Hydatidiform Mole

These moles vary from complete hydatidiform moles clinically, genetically, and histologically. The degree and extent of trophoblastic proliferation and villous edema are decreased compared with that in complete moles. Moreover, most partial moles contain fetal tissue and amnion in addition to placental tissues.

As a result, patients with partial moles typically present with signs and symptoms of an incomplete or missed abortion. Most women will have vaginal bleeding, but because trophoblastic proliferation is slight and only focal, uterine enlargement in excess of gestational age is uncommon. Similarly, preeclampsia, theca-lutein cysts, hyperthyroidism, and other dramatic clinical features are rare (Stefos, 2002). Pre-evacuation β-hCG levels are lower than those for complete moles and often do not exceed 100,000 mIU/mL. For this reason, partial moles are often not identified until after a histologic review of a curettage specimen.

Partial moles have a triploid karyotype (69,XXX, 69,XXY, or less commonly, 69,XYY) that is composed of one maternal and two paternal haploid sets of chromosomes (see Fig. 37-1) (Lawler, 1991). Nontriploid partial moles have been reported, but probably do not actually exist (Genest, 2002b). The coexisting fetus present with a partial mole is nonviable and typically has multiple malformations with abnormal growth (Jauniaux, 1999).

Differential Diagnosis

In reproductive-aged women with vaginal bleeding, diagnoses may include gynecologic causes of bleeding and complications of first-trimester pregnancy (see Chaps. 6, Threatened Abortion, and 8, Diagnosis). Therefore, initial urine or serum β-hCG measurement is invaluable in guiding the diagnostic evaluation.

Diagnosis of Hydatidiform Mole

First-trimester diagnosis of hydatidiform mole is now common because of the routine use of serum β-hCG measurements and transvaginal sonography. An important characteristic of molar pregnancy is its tendency to produce excess β-hCG due to trophoblastic proliferation. As a result, serum β-hCG levels commonly are greater than that expected for the gestational age (Sasaki, 2003).

Although β-hCG levels are helpful, the diagnosis of molar pregnancy more frequently is found sonographically because of the

identifiable diffuse swelling and enlargement of the chorionic villi. Most first-trimester complete moles demonstrate a typical sonographic appearance: a complex, echogenic intrauterine mass containing many small cystic spaces. Fetal tissues and amnionic sac are absent (Fig. 37-4) (Benson, 2000). In contrast, sonographic features of a partial molar pregnancy include a thickened, hydropic placenta with a concomitant fetus (Zhou, 2005).

FIGURE 37-4

Sonogram of complete hydatidiform mole. The classic "snowstorm" appearance is created by the multiple placental vesicles, which completely fill this uterine cavity. *(Courtesy of Dr. Elysia Moschos.)*

Despite the utility of these tools, there are diagnostic limitations. For example, Lazarus and colleagues (1999) reported that β-hCG levels in early molar pregnancies may not always be elevated in the first trimester. These same investigators also found that sonography could lead to a false-negative diagnosis if performed at very early gestational ages, before the chorionic villi have attained the characteristic vesicular pattern (Lazarus, 1999). For example, only 20 to 30 percent of patients may have sonographic evidence suggestive of a partial mole (Johns, 2005; Lindholm, 1999; Sebire, 2001). Consequently, the preoperative diagnosis in early gestations is usually difficult and commonly not made until after a histologic review of the abortal specimen.

Pathologic Diagnosis

HISTOPATHOLOGY

The histopathologic changes typical of a complete and partial mole are listed in Table 37-2. There is no single criterion that distinguishes these hydatidiform moles from each other or from nonmolar gestations.

Complete moles characteristically have two prominent features: (1) trophoblastic proliferation and (2) hydropic villi. In gestations younger than 10 weeks, there are striking differences, however, from these classic findings. In these early gestations, hydropic villi may not be apparent, and molar stroma still may be vascular (Paradinas, 1997). As a result, complete moles now often must be characterized by more subtle morphologic alterations. Unfortunately, this can result in their misclassification as partial moles or nonmolar spontaneous abortions (Fukunaga, 2005; Mosher, 1998).

Partial moles are reliably diagnosed when three or four major diagnostic criteria are demonstrated: (1) two populations of villi, (2) enlarged, irregular, dysmorphic villi (with trophoblast inclusions), (3) enlarged, cavitated villi (≥3 to 4 mm), and (4)

syncytiotrophoblast hyperplasia/atypia (Chew, 2000). Good diagnostic reproducibility still can be achieved in most circumstances using these histologic distinctions of complete and partial mole.

PLOIDY DETERMINATION

Determination of the type of molar gestation clearly can be enhanced by combining histopathology with ploidy determination. *Flow cytometry* is a technique for counting, examining, and sorting cells that are suspended in a stream of fluid. With this tool, multiple physical or chemical characteristics of single cells can be analyzed simultaneously as they flow through an optical electronic detection apparatus. A second cytometry method, *automated image cytometry,* uses optical images of several hundred cell nuclei to identify subtle morphologic changes within tissues. Both techniques can analyze cellular ploidy and can be used to distinguish complete moles (diploid) from partial moles (triploid) (Fig. 37-5). Automated image cytometry, however, has been shown to be more sensitive than flow cytometry in making this distinction (Crisp, 2003a).

Composite diagram of differences between normal hydropic products and partial or complete hydatidiform moles. Tissues that are negative for staining are blue, whereas those positive for staining are brown. The extent (percent cells staining) equates to low, medium, or high expression. Note the progressive increase in Ki-67 and a progressive reduction in p57KIP2 (p57) staining when comparing normal hydropic products of conception with partial and complete moles. First, KI-67 is a proliferation marker and is most prominently expressed in complete moles. In contrast, p57 is a nuclear protein whose gene is paternally imprinted and maternally expressed, meaning that the gene product is produced only in tissues containing a maternal allele. Because complete moles contain only paternal genes, the p57 protein is absent in complete moles. However, this nuclear protein is strongly expressed in spontaneous pregnancy losses with hydropic change. Finally, the DNA ploidy graphs show normal diploid pattern in hydropic contents and in complete moles, whereas the DNA peak is triploid (DNA index 1.5) in partial moles. *(Courtesy of Dr. Raheela Ashfaq.)*

IMMUNOSTAINING

In addition to ploidy analysis, histologic immunostaining techniques also can clarify the diagnosis. p57KIP2 is a nuclear protein whose gene is paternally imprinted and maternally expressed, meaning that the gene product is produced only in tissues containing a maternal allele. Because complete moles contain only paternal genes, the p57KIP2 protein is absent in complete moles (Merchant, 2005). In contrast, this nuclear protein is strongly expressed in normal placentas, spontaneous pregnancy losses with hydropic change, and partial hydatidiform moles (Castrillon, 2001). Accordingly, immunostaining for this nuclear protein is a practical and accurate adjunct to ploidy analysis in the pathologic classification of hydatidiform moles (Castrillon, 2001; Genest, 2002a). p57KIP2 staining has the additional advantage of differentiating hydropic abortuses from complete moles, a distinction not made by ploidy analysis (Merchant, 2005). As a result, complementary use of ploidy analysis and p57KIP2 status now can help to distinguish among a diploid hydropic spontaneous abortion (p57KIP2-positive), a diploid complete mole (p57KIP2-negative), and a triploid partial mole (p57KIP2-positive) (Fig. 37-5) (Crisp, 2003).

In summary, most complete and partial moles are readily identifiable and present little diagnostic difficulty. Those with borderline histology can be resampled in an attempt to confirm the classic features shown in Table 37-2. Ancillary testing with ploidy analysis or p57KIP2 staining is useful for diagnostic, educational, and quality assurance purposes, but these adjunctive tests should not become the mandatory "gold standard" for routine clinical practice because they are neither perfect nor universally available (Genest, 2001).

Treatment

Suction curettage is the preferred method of evacuation regardless of uterine size in patients who wish to remain fertile (Tidy, 2000). Other surgical procedures, however, may be employed for specific indications. For example, hysterectomy may be performed with preservation of the ovaries if a woman wishes surgical sterilization. Additionally, theca-lutein ovarian cysts regress after delivery but may be aspirated if symptomatic (Berkowitz, 1996). Oophorectomy, however, should not be performed except for rare circumstances when torsion of an ovary enlarged by theca-lutein cysts leads to extensive ovarian infarction (Mungan, 1996).

Prior to surgery, patients are evaluated for the presence of associated medical complications. Fortunately, thyroid storm from untreated hyperthyroidism, respiratory insufficiency from trophoblastic emboli, and other severe coexisting conditions are rare. Because of the tremendous vascularity of these placentas, blood products should be available prior to the evacuation of larger

moles, and adequate infusion lines should be established.

At the beginning of the evacuation, the cervix is dilated to admit a 10- to 12-mm plastic Karmen suction cannula (see Fig. 41-17.3). As aspiration of molar tissues ensues, intravenous oxytocin is given. At our institution, 20 units of synthetic oxytocin is mixed with 1 L of crystalloid and infused at rates to achieve uterine contraction. Finally, a thorough, gentle curettage is performed (see Section 41-17, Suction Dilatation and Curettage). Intraoperative sonography may assist in documenting complete evacuation.

Following curettage, because of the possibility of partial mole and its attendant fetal tissue, Rh immune globulin should be given to nonsensitized RhD-negative women. Rh immune globulin, however, may be withheld if the diagnosis of complete mole is certain (Fung Kee, 2003).

Postmolar Surveillance

INCIDENCE OF GESTATIONAL TROPHOBLASTIC NEOPLASIA FOLLOWING HYDATIDIFORM MOLE

Gestational trophoblastic neoplasia (GTN) develops after approximately 15 to 20 percent of complete moles (Soto-Wright, 1995; Wolfberg, 2004). Despite the trend of diagnosing these abnormal pregnancies at earlier gestational ages, this incidence has not decreased (Seckl, 2004; Soto-Wright, 1995). Of those women who develop GTN, three quarters have locally invasive molar disease, and the remaining one quarter develop metastases.

In contrast, GTN develops in only 2 to 4 percent of partial moles following evacuation (Goto, 1993; Lavie, 2005). A lower reported incidence (0.5 percent) of GTN following partial mole in the United Kingdom may reflect more stringent diagnostic criteria (Bagshawe, 1990; Seckl, 2000). Malignant transformation into metastastic choriocarcinoma does occur but fortunately is exceedingly rare (0.1 percent) (Cheung, 2004; Seckl, 2000).

BETA-HUMAN CHORIONIC GONADOTROPIN LEVELS

There are no pathologic or clinical features at presentation that accurately predict which patients ultimately will develop GTN (Rice, 1990). Because of the trophoblastic proliferation that characterizes these neoplasms, serial serum β-hCG levels following evacuation can be used to effectively monitor patients for development of GTN. Therefore, postmolar surveillance with serial quantitative serum β-hCG levels should be the standard. Titers should be monitored following uterine evacuation at least every 1 to 2 weeks until they become undetectable.

Historically, 6 months of surveillance after achieving an undetectable β-hCG levels was recommended for all patients with molar gestation. Unfortunately, poor compliance with 6 months of monitoring has been reportedâ€"especially among indigent women and certain ethnic groups (Allen, 2003; Massad, 2000). In addition, pregnancies conceived within 6 months of achieving undetectable β-hCG levels complicate the monitoring schedule but are otherwise uneventful (Tuncer, 1999). As a result, several studies have evaluated and recent data support the safety of significantly shortening the duration of surveillance. It appears that a single blood sample demonstrating an undetectable level of β-hCG following molar evacuation is sufficient to exclude the possibility of progression to GTN. Patients may then be discharged safely from routine surveillance thereafter (Batorfi, 2004; Feltmate, 2003; Lavie, 2005; Wolfberg, 2004).

Pregnancies can occur during the monitoring period, and the resulting β-hCG production can hinder detection of progression to GTN (Allen, 2003). For this reason, women are encouraged to use effective contraception until achieving a β-hCG titer of less than 5 mIU/mL or the threshold of the individual assay. Oral contraceptive pills decrease the likelihood of pregnancy compared with less effective barrier contraception and do not increase the risk of GTN (Curry, 1989). Injectable medroxyprogesterone acetate is particularly useful when poor compliance is anticipated (Massad, 2000). In contrast, intrauterine devices are not to be inserted until the β-hCG level is undetectable because of the risk of uterine perforation if an invasive mole is present.

Prophylactic Chemotherapy

The purpose of administering chemotherapy at the time of molar evacuation is to prevent the development of GTN in high-risk patients who are unlikely to be compliant with β-hCG surveillance. For example, in a prospective, double-blind clinical trial of 60 women who had high-risk complete moles, Limpongsanurak (2001) randomly assigned women to receive either dactinomycin or

placebo at the time of evacuation. Prophylactic chemotherapy reduced the incidence of GTN from 50 to 14 percent, but toxicity was significant. In clinical practice, the correct classification of high-risk complete moles, however, is extremely difficult because there is no universally accepted combination of risk factors that accurately predicts GTN development. Moreover, regardless of how a high-risk complete mole is defined, few women ultimately will be assigned to this group. Thus, identification at diagnosis of the women who potentially could benefit from prophylactic chemotherapy is of little overall clinical importance (Parazzini, 1988b).

As a result, the indications for prophylactic chemotherapy remain controversial (Murad, 1990). Rarely, this strategy may be considered in patients with complete moles and multiple risk factors (age greater than 40 years, previous history of molar pregnancy, and excessively high β-hCG titer), particularly if postevacuation β-hCG testing is unavailable or poor compliance during surveillance is expected (Berkowitz, 1996). For this reason, prophylactic chemotherapy is not offered routinely and typically is practiced outside the United States and Europe (Uberti, 2006).

Ectopic Molar Pregnancy

The true incidence of ectopic gestational trophoblastic disease approximates 1.5 per 1 million births (Gillespie, 2004). More than 90 percent of suspected cases will reflect an overdiagnosis of florid extravillous trophoblastic proliferation in the fallopian tube (Burton, 2001; Sebire, 2005b). Other sites of ectopic implantation are even less common (Bailey, 2003). As with any ectopic pregnancy, initial management usually involves surgical removal of the conceptus and histopathologic evaluation.

Coexisting Fetus

The estimated incidence of twin pregnancy consisting of hydatidiform mole and a coexisting fetus is 1 per 20,000 to 100,000 pregnancies. Sebire (2002b) described the outcome of 77 twin pregnancies, each composed of a complete mole and a healthy co-twin. Of this group, 24 women chose to have an elective termination, and 53 continued their pregnancies. Twenty-three gestations aborted spontaneously at less than 24 weeks, 2 were terminated because of severe preeclampsia, and 28 pregnancies lasted at least 24 weeksâ€”resulting in 20 live births. The authors demonstrated that coexisting complete moles and healthy co-twin pregnancies have a high risk of spontaneous abortion, but approximately 40 percent result in live births.

In this study, the risk of progression to GTN was 16 percent in first-trimester terminations and not significantly higher (21 percent) in women who continued their pregnancies. Previous reports with fewer patients had suggested a higher risk of developing GTN in those continuing their pregnancies (Matsui, 2000; Steller, 1994). Because the risk of malignancy is unchanged with advancement of gestational age, pregnancy continuation may be allowed, provided that severe maternal complications are controlled and fetal growth is normal. Fetal karyotyping to confirm a normal chromosomal pattern is also recommended (Marcorelles, 2005; Matsui, 2000).

GESTATIONAL TROPHOBLASTIC NEOPLASIA

This term encompasses primarily pathologic entities that are characterized by aggressive invasion of the endometrium and myometrium by trophoblastic cells. Histologic categories include common tumors such as the *invasive mole* and *gestational choriocarcinoma,* as well as the rare *placental site trophoblastic tumor* and *epithelioid trophoblastic tumor.* Although these histologic types have been characterized and described, in most cases of GTN there is no tissue available for pathologic study. For this reason, most cases of GTN are diagnosed and managed clinically.

Gestational trophoblastic neoplasia typically develops with or follows some form of pregnancy, but occasionally, an antecedent gestation cannot be confirmed with certainty. Most of cases follow a hydatidiform mole. Rarely, GTN develops after a live birth, miscarriage, or termination. Many of the reported nonmolar cases actually may represent disease due to an unrecognized early molar pregnancy (Sebire, 2005a).

Histologic Classification

INVASIVE MOLE

This is a common manifestation of GTN characterized by the presence of whole chorionic villi that accompany excessive trophoblastic overgrowth and invasion. These tissues penetrate deep into the myometrium, sometimes involving the peritoneum, adjacent parametrium, or vaginal vault. Such moles are locally invasive but generally lack the pronounced tendency to develop

widespread metastases typical of choriocarcinoma. Invasive moles originate almost exclusively from complete or partial molar gestations (Sebire, 2005a).

GESTATIONAL CHORIOCARCINOMA

This extremely malignant tumor is comprised of sheets of anaplastic cytotrophoblast and syncytiotrophoblast cells with prominent hemorrhage, necrosis, and vascular invasion (Fig. 37-6). Unlike molar disease, however, chorionic villi are characteristically absent. Gestational choriocarcinomas initially invade the endometrium and myometrium but tend to develop early blood-borne systemic metastases (Fig. 37-7).

Computed-tomography (CT) scan of choriocarcinoma invading the uterus.

Although most cases develop following evacuation of a molar pregnancy, these tumors also may less commonly follow a nonmolar pregnancy. Alternatively, primary "nongestational" choriocarcinoma ovarian germ cell tumors have an identical histologic appearance and are in part distinguished by the absence of any preceding pregnancy event (see Chap 36, Choriocarcinoma).

Gestational choriocarcinoma develops in approximately 1 in 30,000 nonmolar pregnancies. Two thirds of such cases follow term pregnancies, and a third develop after a spontaneous abortion or pregnancy termination. Tidy (1995) reviewed 100 patients with nonmolar gestational choriocarcinoma and found that 62 presented after a live birth, 6 after a live birth preceded by a molar pregnancy, and 32 after a nonmolar abortion. Vaginal bleeding was the most common symptom in all groups (Tidy, 1995). For this reason, abnormal bleeding for more than 6 weeks following any pregnancy should be evaluated with β-hCG testing to exclude a new pregnancy or GTN (Soper, 2004).

In those cases following term pregnancies, unanticipated choriocarcinoma is detected occasionally in an otherwise normal-appearing placenta at delivery. More commonly, however, the diagnosis of choriocarcinoma is delayed due to subtle signs and symptoms of disease in patients with an antecedent normal pregnancy. For example, Rodabaugh and colleagues (1998) found that in 89 percent of cases, the preceding pregnancy had produced an uncomplicated live birth. Hydrops, however, was a notable complication in the remaining fetuses.

In part because of the typical delay to diagnosis, choriocarcinomas following term pregnancies have a significantly higher mortality rate than GTN following nonmolar abortions (Olive, 1984; Tidy, 1995). Rodabaugh and associates (1998) at the New England

Trophoblastic Disease Center reported a 14-percent mortality rate in 44 women diagnosed with choriocarcinoma following a term pregnancy. More than half of the patients presenting with brain metastases or placental site trophoblastic tumors have a preceding term gestation (Feltmate, 2001; Newlands, 2002). The frequency of these high-risk features also helps to explain the poorer prognosis for choriocarcinoma following a term pregnancy.

PLACENTAL SITE TROPHOBLASTIC TUMOR

This tumor consists predominantly of intermediate trophoblasts at the placental site and is a rare variant of GTN with unique disease behavior (Scully, 1981). Placental site trophoblastic tumors can follow any type of pregnancy but develop more commonly following a normal pregnancy. They tend to infiltrate only within the uterus, disseminate late in their course, and produce low levels of β-hCG relative to their mass (Twiggs, 1998). When this tumor does spread, however, the pattern mirrors that of gestational choriocarcinoma. Fifteen percent of all reported cases were fatal (Baergen, 2006).

Hysterectomy is the primary method of treatment for nonmetastatic placental site trophoblastic tumor due to its relative insensitivity to chemotherapy (Feltmate, 2001; Papadopoulos, 2002). Alternatively, the combination of operative hysteroscopic resection followed by chemotherapy may be an option to preserve fertility in particularly motivated patients (Machtinger, 2005).

Metastatic placental site trophoblastic tumor has a much poorer prognosis than the other, more common, types of metastatic GTN (Hassadia, 2005). As a result, aggressive combination chemotherapy is indicated. A regimen of etoposide, methotrexate, and dactinomycin alternating with etoposide and cisplatin (EMA/EP) is the most effective treatment (Newlands, 2000). Radiation, however, also may have a role in some situations. Papadopoulos and colleagues (2002) have reported a 79-percent survival rate in 34 patients treated by multimodality therapy.

EPITHELIOID TROPHOBLASTIC TUMOR

This rare trophoblastic tumor is distinct from gestational choriocarcinoma and placental site trophoblastic tumor. The preceding pregnancy event may be remote, or in some cases a prior gestation cannot be confirmed. Epithelioid trophoblastic tumor develops from neoplastic transformation of chorionic-type intermediate trophoblast. Microscopically, this tumor resembles placental site trophoblastic tumor, but the cells are smaller and display less nuclear pleomorphism. Grossly, epithelioid trophoblastic tumor grows in a nodular fashion rather than the infiltrative pattern of placental site trophoblastic tumor. Hysterectomy is the primary method of treatment, but approximately 20 to 25 percent of patients will present with metastatic disease. Currently, there are too few reported cases to evaluate the efficacy of chemotherapy (Shih, 1998).

Clinical Classification

DIAGNOSIS

Most GTN cases are diagnosed clinically using hormonal evidence of persistent trophoblastic tissue (Table 37-3). Tissue is infrequently available for pathologic diagnosis. As a result, most centers in the United States diagnose GTN on the basis of rising β-hCG values or a persistent plateau of β-hCG values for at least 3 weeks. Unfortunately, there is a lack of uniformity in the definition of a persistent plateau. Additionally, the diagnostic criteria are less stringent in the United States than in Europe partly because of concern that some patients may be lost to follow-up if stricter criteria are used.

Table 37-3 Criteria for the Diagnosis of Gestational Trophoblastic Neoplasia
1. Plateau of β-hCG lasts for four measurements over a period of 3 weeks or longer (days 1, 7, 14, and 21).
2. Rise of β-hCG of 3 weekly consecutive measurements or longer, over a period of 2 weeks or more (days 1, 7, and 14).
3. β-hCG remains elevated for 6 months or more.
4. Histologic diagnosis of choriocarcinoma.

FIGO=International Federation of Gynecology and Obstetrics; hCG= beta human chorionic gonadotropin. From FIGO Oncology Committee, 2002, with permission.

When serologic criteria are met for GTN, a new intrauterine pregnancy should be excluded using β-hCG levels correlated with

sonographic findings, especially when there has been a long delay in monitoring of serial β-hCG levels or noncompliance with contraception or both.

DIAGNOSTIC EVALUATION

Patients with GTN undergo a thorough pretreatment assessment to determine the extent of disease. The initial evaluation includes a pelvic examination, chest radiograph, and abdominal-pelvic computed tomographic (CT) scan (Garner, 2004; Ngan, 1998). Pulmonary lesions should prompt CT scanning of the chest and brain. In addition, positron-emission tomography/computed tomography (PET/CT) may be useful in the evaluation of occult choriocarcinoma when conventional imaging fails to identify metastatic disease (Numnum, 2005).

STAGING

Gestational trophoblastic neoplasia is staged anatomically based on a system adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 37-4). Patients at low risk for therapeutic failure are distinguished from those at high risk using the modified prognostic scoring system of the World Health Organization (WHO) (Table 37-5). Patients with WHO scores of 0 to 6 are considered to have low-risk disease, whereas those with a score of 7 or higher are assigned to the high-risk GTN group. For the most accurate description of these patients, the Roman numeral corresponding to FIGO stage is separated by a colon from the sum of all the actual risk factor scoresâ€œfor example, stage II:4 or stage IV:9 (FIGO Oncology Committee, 2002).

Table 37-4 FIGO Anatomic Staging

Stage I	Disease confined to the uterus
Stage II	GTN extends outside of the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs, with or without known genital tract involvement
Stage IV	All other metastatic sites (brain, liver)

FIGO = International Federation of Gynecology and Obstetrics; GTN = gestational trophoblastic neoplasia.

Table 37-5 Modified WHO Prognostic Scoring System as Adapted by FIGO

Scores	**0**	**1**	**2**	**4**
Age (yr)	<40	≥40	â€”	â€”
Antecedent pregnancy	Mole	Abortion	Term	â€”
Interval months from index pregnancy	<4	4â€œ6	7â€œ12	≥13
Pretreatment serum β-hCG (mIU/mL)	$<10^3$	10^3 â€œ$<10^4$	10^4 â€œ$<10^5$	$\geq 10^5$
Largest tumor size (including uterus)	â€”	3â€œ<5 cm	≥5 cm	â€”
Site of metastases	Lung	Spleen, kidney	Gastro-intestinal	Liver, brain
Number of metastases	â€”	1â€œ4	5â€œ8	>8
Previous failed chemotherapy drugs	â€”	â€”	1	≥2

Low risk = WHO score of 0 to 6; high risk = WHO score of ≥ 7.

FIGO = International Federation of Gynecology and Obstetrics; hCG = human chorionic gonadotropin; WHO = World Health Organization.

This addition of risk scoring to anatomic staging has been shown to best reflect the disease behavior (Ngan, 2004). Women with high risk scores are more likely to have tumors that are resistant to single-agent chemotherapy. They are therefore treated initially with combination chemotherapy. Although patients with stage I disease infrequently have a high risk score, those with stage IV disease invariably have a high risk score.

The FIGO classification system has been reported to be a better predictor of disease-free survival than the WHO scoring system (Bjorge, 2002). Women diagnosed with FIGO stage I, II, and III GTN have a survival rate approaching 100 percent (Table 37-6) (Berkowitz, 1996).

Table 37-6 Survival of Gestational Trophoblastic Neoplasia by FIGO Stage

Stage	Survival	Percent
I	424/424	100
II	27/27	100
III	130/131	99
IV	14/18	78

FIGO = International Federation of Gynecology and Obstetrics.

NONMETASTATIC DISEASE

Invasive moles arising from complete molar gestations comprise most cases of nonmetastatic GTN. Fifteen to 20 percent of complete moles develop locally invasive disease after evacuation, compared with only 2 to 4 percent of partial moles. Placental site trophoblastic tumors and epithelioid trophoblastic tumors are other rarer causes of nonmetastatic GTN. Locally invasive trophoblastic tumors may perforate through the myometrium and lead to intraperitoneal bleeding (Mackenzie, 1993). Alternatively, vaginal hemorrhage can follow tumor erosion into uterine vessels, or necrotic tumor may involve the uterine wall and serve as a nidus for infection. Fortunately, the prognosis is excellent for all types of nonmetastatic disease despite these possible manifestations (Lurain, 1982).

METASTATIC DISEASE

Choriocarcinomas originating from complete molar gestations comprise most cases of metastatic GTN. Four to five percent of complete moles develop metastatic choriocarcinoma after evacuation. The incidence following any other type of molar or nonmolar gestation is exceedingly rare. Choriocarcinomas have a propensity to distant spread and should be suspected in any woman of reproductive age with metastatic disease from an unknown primary (Tidy, 1995). Moreover, because of this tendency, chemotherapy is indicated whenever choriocarcinoma is diagnosed histologically.

Although many patients are largely asymptomatic, metastatic GTN is highly vascular and prone to severe hemorrhage either spontaneously or during biopsy. Menorrhagia is a common presenting symptom. The most common sites of spread are the lungs (80 percent), vagina (30 percent), pelvis (20 percent), liver (10 percent), and brain (10 percent) (Fig. 37-8). Patients with pulmonary metastases typically have asymptomatic lesions identified on routine chest radiograph and infrequently present with cough, dyspnea, hemoptysis, or signs of pulmonary hypertension (Kumar, 1988). In patients with the early development of respiratory failure that requires intubation, the overall outcome is poor. Hepatic or cerebral involvement is encountered almost exclusively in patients who have had an antecedent nonmolar pregnancy and a protracted delay in tumor diagnosis (Newlands,

2002). These women may present with associated hemorrhagic events. Virtually all patients with hepatic or cerebral metastases have concurrent pulmonary or vaginal involvement or both. Great caution is used in attempting excision of any metastatic disease site due to the risk of profuse hemorrhage. Thus, this practice is almost uniformly avoided except in extenuating circumstances of life-threatening brain stem herniation or chemotherapy-resistant disease.

Treatment

SURGICAL MANAGEMENT

Most patients diagnosed with postmolar GTN have persistent tumor confined to the endometrial cavity and are treated primarily with chemotherapeutic agents. Repeat dilatation and curettage generally are avoided to prevent morbidity and mortality caused by uterine perforation, hemorrhage, infection, uterine adhesions, and anesthetic complications (Soper, 2004). Accordingly, second evacuations typically are not performed in the United States unless patients have persistent uterine bleeding and substantial amounts of retained molar tissue. Repeat uterine curettage is a much more standard part of the management of postmolar GTN in Europe and has been shown to reduce significantly both the number of patients needing any further treatment and the number of courses in those who do require chemotherapy (Pezeshki, 2004; van Trommel, 2005). A second evacuation followed by continued surveillance, however, is a less attractive option for poorly compliant patients than single-agent chemotherapy (Allen, 2003; Massad, 2000).

Hysterectomy may play several roles in the treatment of GTN. First, it may be performed primarily to treat placental site trophoblastic tumors, epithelioid trophoblastic tumors, or chemotherapy-resistant disease. In addition, severe uncontrollable vaginal or intra-abdominal bleeding may necessitate hysterectomy as an emergency procedure (Chao, 2002). Because of these more extreme indications, most women undergoing hysterectomy have elevated pretreatment risk scores, unusual pathology, and higher mortality (Pisal, 2002). Finally, adjuvant hysterectomy decreases the total dose of chemotherapy needed to achieve clinical remission in low-risk GTN. Patients with disease apparently confined to the uterus who do not desire future fertility should be counseled about this option (Suzuka, 2001).

Residual lung metastases may persist in 10 to 20 percent of patients achieving clinical remission of GTN after completion of chemotherapy. An undetectable β-hCG reflects clinical remission. These patients do not appear to have an increased risk of relapse

compared with those having normal chest radiographs or CT scans. Thoracotomy is not required in these situations (Powles, 2006). Surgical resection of metastases is performed only when chemotherapy-resistant disease is suspected.

CHEMOTHERAPY FOR LOW-RISK GTN

Methotrexate

This agent is the most common treatment for low-risk disease. Several intramuscular regimens have been reported, with complete remission rates ranging from 60 to 80 percent (Table 37-7). The Gynecologic Oncology Group (GOG) conducted a prospective cohort study (protocol 79) of weekly methotrexate that established an effective dose of 30 mg/m^2 with minimal toxicity (Homesley, 1988, 1990). Charing Cross Hospital investigators use an 8-day alternating regimen of methotrexate 50 mg on treatment days 1, 3, 5, and 7 and oral folinic acid 7.5 mg taken orally on days 2, 4, 6, and 8. Treatment is repeated every 2 weeks until β-hCG is undetectable (McNeish, 2002). University of Sheffield investigators demonstrated similar success with the same regimen (Khan, 2003). Alternatively, intramuscular methotrexate 0.4 mg/kg per day for 5 consecutive days on alternating weeks is another effective option, but it requires a median of 20 to 30 clinic visits for chemotherapy administration to achieve remission (Schorge, 2003; Soper, 1994a).

Table 37-7 Intramuscular Methotrexate Regimens for Treatment of Low-Risk GTN

Frequency	Dose	Population Studied	CR Rate (%)	First Author
Weekly	30â€“50 mg/m^2	Nonmetastatic GTN	74â€“81	Homesley, 1988
Days 1,3,5,7	50 mg/d	Low-risk GTN	67â€“72	McNeish, 2002
				Khan, 2003
5-Day	0.4 mg/kg/d	Low-risk GTN (majority)	60	Soper, 1994a

CR = clinical remission (calculated for first-line treatment without needing alternative chemotherapy); GTN = gestational trophoblastic neoplasia.

As discussed more fully in Chapter 27, Methotrexate, methotrexate is a folic acid antagonist that inhibits DNA synthesis by causing an acute intracellular deficiency of folate coenzymes. Mild stomatitis is the most common side effect, but other serosal symptoms, especially pleurisy, develop in up to one quarter of patients treated with low-dose methotrexate. Pericarditis, peritonitis, and pneumonitis are infrequent (Sharma, 1999). Toxicity develops more frequently with the more intense daily regimens compared with weekly administration despite routine folinic acid "rescue" of normal mucosal and serosal cells (Gleeson, 1993).

In addition to intramuscular administration, methotrexate intravenous infusion has proved successful. For example, a 100 mg/m^2 bolus followed by 200 mg/m^2 given during 12 hours has a 65-percent complete response rate (Garrett, 2002). Folinic acid rescue is not necessary using this regimen due to the nontoxic levels of methotrexate reached 24 hours after infusion (Allen, 2003; Wong, 2000). Because this regimen is usually successful with a single dose, it may be particularly effective in poorly compliant patients by shortening the treatment duration and reducing the number of required visits (Schorge, 2003). Oral methotrexate has few indications in the management of GTN (Farley, 2005).

Dactinomycin

This chemotherapy agent is used less commonly for the primary treatment of low-risk disease. The GOG conducted a phase II trial of "pulse" dactinomycin, 1.25 mg/m^2 administered as an intravenous bolus dose every 2 weeks (protocol 69). Ninety-four percent of patients without metastatic disease achieved remission (Petrilli, 1987). In addition, dactinomycin was superior to methotrexate in a recent prospective study of 46 patients. Investigators found that the pulse dactinomycin arm had a 94-percent success rate compared with a 50-percent success rate for weekly intramuscular methotrexate given in doses of 30 mg/m^2 (Gilani, 2005). The GOG is currently performing a larger prospective, randomized study (protocol 174) using the same dactinomycin and methotrexate regimens for low-risk GTN to directly compare treatment efficacy and toxicity. Pulse dactinomycin has similar efficacy as a 5-day course of dactinomycin, 12 μg/kg each day, but is considered the treatment of choice because of its greater convenience and lower

cost (Schlaerth, 1984).

Patients who do not respond to an initial single-agent chemotherapeutic regimen should have their score recalculated using the modified WHO prognostic scoring system. Most women still will be considered low risk and may be switched to single-agent second-line therapy. Methotrexate-resistant GTN often responds to dactinomycin (Chen, 2004). The GOG recently demonstrated a 73-percent success rate in a phase II trial of pulse dactinomycin as salvage treatment for 40 patients with methotrexate-resistant GTN (protocol 176). Etoposide is used less commonly in this setting but is also effective (Mangili, 1996). Patients treated initially with pulse dactinomycin who develop resistant GTN still may be treated successfully with the 5-day course of dactinomycin (Kohorn, 2002). Alternatively, single-agent methotrexate or etoposide is effective in these cases (Matsui, 2005).

CHEMOTHERAPY FOR HIGH-RISK GTN

Etoposide, methotrexate, and dactinomycin alternating with cyclophosphamide and vincristine (EMA/CO) chemotherapy is a well-tolerated and highly effective regimen for high-risk GTN that should be considered the primary treatment in most circumstances (see Chap 27, Cyclophosphamide). Response rates are comparable whether patients are treated primarily or after failure of single-agent chemotherapy. Bower and colleagues (1997) reported a 78-percent complete remission rate in 272 consecutive women. Similarly, other investigators have observed a 71- to 77-percent complete remission rate (Escobar, 2003; Soper, 1994b).

Patients with high-risk disease who become refractory to or relapse from EMA/CO chemotherapy may be treated effectively by replacing the cyclophosphamide and vincristine component with etoposide and cisplatin (EMA/EP). Newlands and colleagues (2000) reported an 88-percent survival rate among 34 patients using this regimen. Other alternatives for second- or third-line therapy include paclitaxel and alternating etoposide and cisplatin (TE/TP) and cisplatin and bleomycin combined with either vinblastine (VPB) or etoposide (BEP) (Azab, 1989; DuBeshter, 1989; Lurain, 2005; Osborne, 2004). High-dose chemotherapy and hematopoietic stem cell support are unproven for refractory GTN (El Helw, 2005).

BRAIN METASTASES

Patients with GTN metastatic to the brain usually can be cured with aggressive multimodality therapy that may include chemotherapy, surgery, and radiation. In addition, emergency craniotomy may be indicated in selected patients who display rapidly deteriorating signs (Semple, 2004; Yang, 2005).

Newlands and colleagues (2002) reported an 80-percent survival rate among 39 patients treated by EMA/CO with an escalated dose of methotrexate and folinic acid. Intrathecal methotrexate also was administered until β-hCG levels were undetectable. Surgical removal of the main active site of disease was performed in 16 patients. Four of the 39 women died within 8 days of presentation. The presence of both liver and brain metastases was a particularly adverse prognostic combination, with only 1 of 5 patients surviving. Whole-brain radiation therapy also may be an efficacious adjunct to combination chemotherapy and surgery, but at the cost of inducing intellectual impairment in patients who are cured (Evans, 1995; Schechter, 1998).

POSTTREATMENT SURVEILLANCE

Monitoring of patients with stage I, II, or III GTN consists of weekly β-hCG measurements until the level is undetectable for 3 weeks, followed by monthly titers until the level is undetectable for 12 months. Women with stage IV disease are followed for 24 months because of the greater risk of late relapse. Patients are encouraged to use effective contraception, as outlined earlier, during the entire surveillance period (Berkowitz, 1996).

SUBSEQUENT PREGNANCY OUTCOME

Patients may expect a normal reproductive outcome after achieving remission from gestational trophoblastic disease. Women having a pregnancy affected by a histologically confirmed complete or partial mole may be counseled that the risk of a repeat mole in a subsequent pregnancy is 1 to 2 percent (Berkowitz, 1994). Most will be of the same type of mole as the preceding pregnancy (Sebire, 2003). Pregnancy after combination EMA/CO chemotherapy for GTN also has a high probability of success and a favorable outcome (Lok, 2003).

SECONDARY TUMORS

Etoposide-based combination chemotherapy has been associated with an increased risk of leukemia, colon cancer, melanoma, and

breast cancer up to 25 years after treatment for GTN. An overall 50-percent excess risk was observed (Rustin, 1996). Etoposide therefore is reserved to treat patients who are likely to be resistant to single-agent chemotherapy and, in particular, patients with high-risk metastatic disease (Schorge, 2000).

PHANTOM β-HCG

Occasionally, persistent mild elevations of serum β-hCG are detected that lead physicians erroneously to treat patients with cytotoxic chemotherapy or hysterectomy or both when, in reality, no true β-hCG or trophoblastic disease is present (Cole, 1998; Rotmensch, 2000). This "phantom" β-hCG reading results from the presence in serum of heterophilic antibodies that interfere with the β-hCG immunoassay and cause a false-positive result.

There are several ways to clarify the diagnosis. First, phantom β-hCG can be demonstrated by a negative urine pregnancy test, but only if the patient's serum β-hCG level is significantly higher than the detection threshold of the urine test. Second, performing serial dilutions of the serum sample results in a proportional decrease in the β-hCG level if β-hCG is truly present; phantom β-hCG measurements will be unchanged. In addition, if phantom β-hCG is suspected, some specialized laboratories may be able to block the heterophilic antibodies. Lastly, a different β-hCG assay performed using an alternate method may accurately demonstrate the absence of true β-hCG (Cole, 1998; Olsen, 2001; Rotmensch, 2000).

QUIESCENT GESTATIONAL TROPHOBLASTIC DISEASE

Patients with persistent mild elevations (usually in the range of 50 mIU/mL or less) of true β-hCG may have a dormant premalignant condition if no tumor is identified by physical examination or imaging studies (Khanlian, 2003). In this instance, phantom β-hCG also should be conclusively excluded as a possibility. The low β-hCG titers may persist for months or years before disappearing. Chemotherapy and surgery usually have no effect. Hormonal contraception may be helpful in lowering titers to an undetectable level, but patients should be monitored closely because metastatic GTN may develop eventually (Khanlian, 2003; Kohorn, 2002).

ANATOMY: INTRODUCTION

A gynecologic surgeon must be familiar with the anatomy of the female pelvis and lower abdominal wall. Over the past 20 years, the rote knowledge of pelvic anatomy has been complemented by a better understanding of the neuromuscular physiology that governs pelvic function. This chapter presents a broad overview of these relationships.

ANTERIOR ABDOMINAL WALL

The anterior abdominal wall provides core support to the human torso, confines abdominal viscera, and contributes muscular action for functions such as respiration and elimination. In gynecology, comprehensive knowledge of the layered structure of the anterior abdominal wall is needed to effectively enter the peritoneal cavity for surgery without neurovascular complications.

Skin

The term *Langer lines* describes the orientation of dermal fibers within the skin. In the anterior abdominal wall, they are arranged in a primarily transverse orientation. As a result, vertical skin incisions sustain more lateral tension and thus in general develop wider scars. In contrast, low transverse incisions, such as the Pfannenstiel, follow Langer lines and lead to superior cosmetic results.

Subcutaneous Layer

This layer of the anterior abdominal wall can be separated into a superficial, predominantly fatty layer known as *Camper fascia* and a deeper, more membranous layer known as *Scarpa fascia.* Camper and Scarpa fasciae are not discrete layers but represent a continuum of the subcutaneous tissue layer.

CLINICAL CORRELATION

Scarpa fascia is better developed in the lower abdomen and can be best identified in the lateral portions of a low transverse incision, just superficial to the rectus fascia. In contrast, this fascia is rarely recognized during midline incisions.

Rectus Sheath

The aponeuroses of the external oblique, internal oblique, and tranversus abdominis muscles (flank muscles) conjoin to create the *rectus sheath* (Fig. 38-1). In the lower abdomen, transition from the muscular to the aponeurotic component of the external oblique muscles takes place along a vertical line through the anterosuperior iliac spine. Transition from muscle to aponeurosis for the internal oblique and transversus abdominis takes place more medially. For this reason, muscle fibers of the internal oblique are often noted below the aponeurotic layer of the external oblique during low transverse incisions.

Muscles of the anterior abdominal wall. *(From Cundiff, 2002, with permission.)*

The anatomy of the rectus sheath above and below the *arcuate line* has significance to the surgeon (Fig. 38-2). This line defines the location at which the rectus sheath passes entirely anterior to the rectus muscles and typically lies midway between the umbilicus and pubic symphysis. Above the arcuate line, the rectus sheath lies anterior and posterior to the rectus muscles. At this level, the anterior rectus sheath is formed by the aponeurosis of the external oblique and the split aponeurosis of the internal oblique muscles. The posterior rectus sheath is formed by the split aponeurosis of the internal oblique muscle and the aponeurosis of the tranversus abdominis muscle. Below the arcuate line, all aponeurotic layers pass anterior to the rectus muscles. Thus, in the lower abdomen, the posterior surface of the rectus muscles is in direct contact with the transversalis fascia.

Tranverse sections of the anterior abdominal wall. **A.** Above the arcuate line. **B.** Below the arcuate line.

CLINICAL CORRELATION

In the lower abdomen, the aponeuroses of the internal oblique and tranversus abdominis muscles fuse. Therefore, only two layers are identified during low transverse fascial incisions (see Section 41-2, Pfannenstiel Incision).

Similar to the fibers of the skin, the flank muscles fibers are oriented primarily transversely. Therefore, suture lines in a vertical fascial incision are placed under more tension than those in a transverse incision. As a result, vertical fascial incisions are more prone to dehiscence and hernia formation.

Tranversalis Fascia

This thin layer of fibrous tissue lies between the inner surface of the transversus abdominis muscle and preperitoneal fat and thus serves as part of the general fascial layer that lines the abdominal cavity (see Fig. 38-2) (Memon, 1999). Inferiorly, the transversalis fascia blends with the periosteum of the symphysis pubis at a point lateral to the insertion of the rectus muscle.

CLINICAL CORRELATION

This fascia is best recognized as the layer bluntly or sharply dissected off the anterior surface of the bladder during entry into the abdominal cavity.

Peritoneum

The peritoneum that lines the inner surface of the abdominal walls is termed *parietal peritoneum.* In the anterior abdominal wall there are five vertical folds of parietal peritoneum that are raised by different structures. All five converge toward the umbilicus and are known as *umbilical ligaments.*

The single *median umbilical ligament* is formed by the urachus, an obliterated tube that extends from the apex of the bladder to the umbilicus. In fetal life, the urachus, or allantoic diverticulum, extends from the fetal hindgut to the umbilical cord. Transection of a patent urachus can result in extravasation of urine into the abdominal cavity. The paired *medial umbilical ligaments* are formed by the obliterated umbilical arteries that connected the internal iliac arteries to the umbilical cord in fetal life. Lastly, the paired *lateral umbilical ligaments* contain the inferior epigastric vessels.

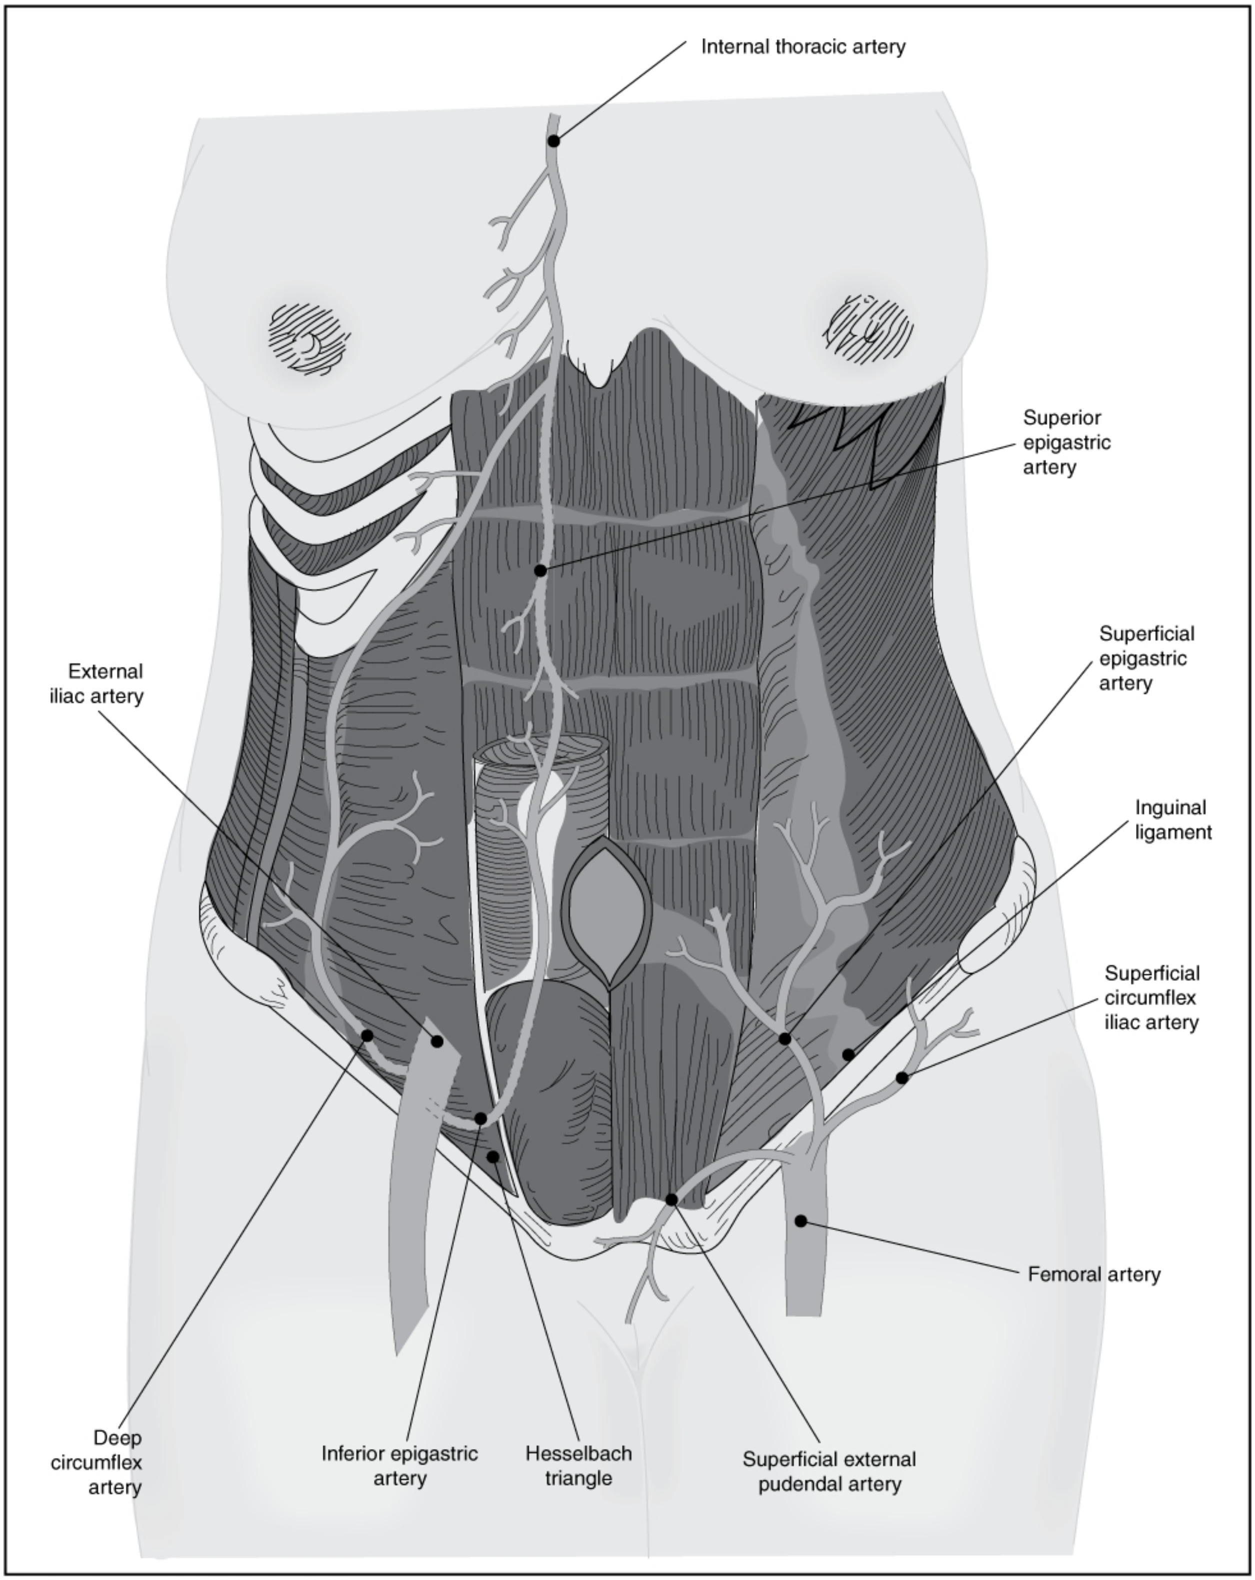
Blood Supply

Laceration of abdominal wall vessels can increase blood loss and risk of postoperative hematoma formation. Accordingly, familiarity with the origin and course of vessels that supply the anterior abdominal wall structures is critical when performing laparotomy and laparoscopy.

FEMORAL BRANCHES

The superficial epigastric, superficial circumflex iliac, and external pudendal arteries arise from the femoral artery just below the inguinal ligament in the region of the femoral triangle (Fig. 38-3). These vessels supply the skin and subcutaneous layers of the anterior abdominal wall and mons pubis. The *superficial epigastric vessels* course diagonally toward the umbilicus similar to the inferior "deep" epigastric vessels.

FIGURE 38-3



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

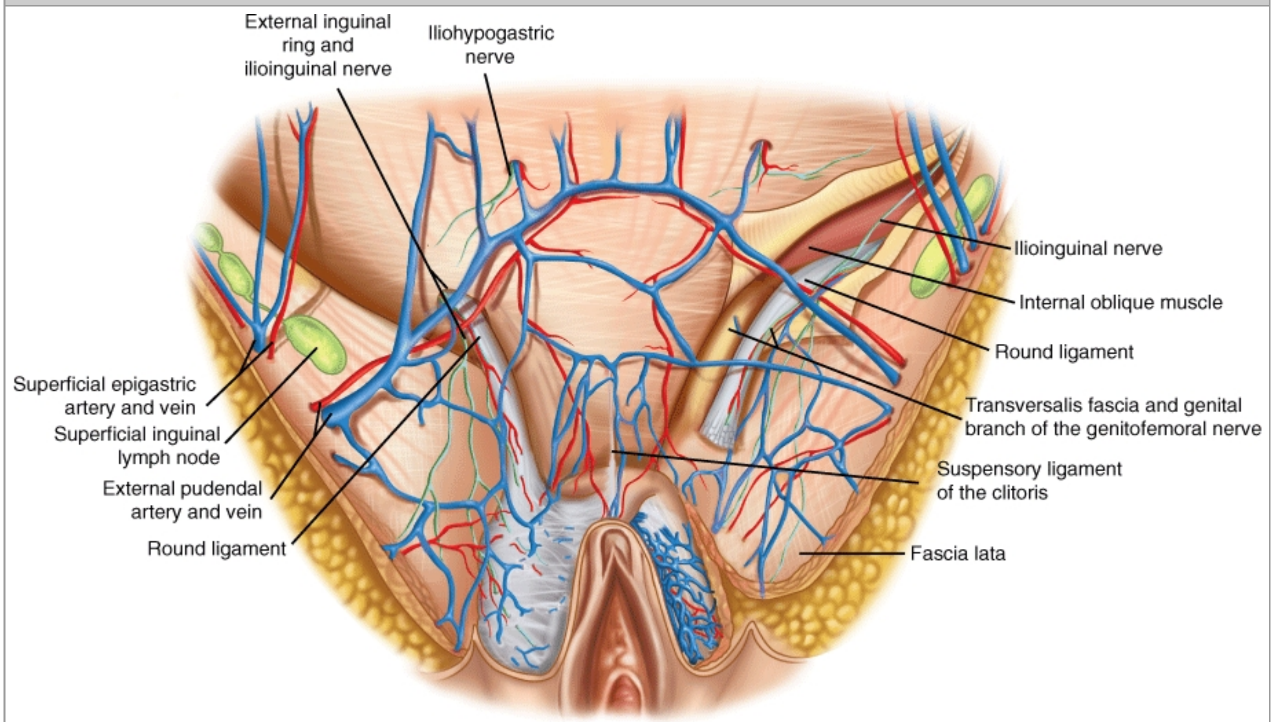
Vessels of the anterior abdominal wall. *(From Cundiff, 2002, with permission.)*

Clinical Correlation

During low transverse skin incisions, the superficial epigastric vessels usually can be identified halfway between the skin and the rectus fascia, several centimeters from the midline. During laparoscopic procedures in thin patients, these vessels can be identified by transillumination (see Section 41-28, Laparoscopy).

The external pudendal vessels form rich anastomoses with their contralateral equivalents and with other superficial branches. These anastomoses account for the extensive bleeding often encountered with incisions made in the mons pubis area (Fig. 38-4).

FIGURE 38-4



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pubic and inguinal regions. *(From Reiffenstuhl, 1975, with permission.)*

EXTERNAL ILIAC BRANCHES

The *inferior "deep" epigastric vessels* and *deep circumflex iliac vessels* are branches of the external iliac vessels (see Fig. 38-3). They supply the muscles and fascia of the anterior abdominal wall. The inferior epigastric vessels initially course lateral to and then posterior to the rectus muscles, which they supply. They then pass anterior to the posterior rectus sheath and course between the sheath and the rectus muscles. Near the umbilicus, the inferior epigastric vessels anastomose with the superior epigastric artery and veins, branches of the internal thoracic vessels.

Clinical Correlation

The inferior epigastric vessels also can be injured during accessory trocar placement with laparoscopy. Techniques to avoid their injury are discussed in Section 41-28, Laparoscopy. In addition, low transverse abdominal incisions that extend beyond the lateral margins of the rectus muscles can lead to vessel laceration with severe hemorrhage or anterior abdominal wall hematoma formation. These vessels should be identified and ligated when performing a Maylard incision (see Section 41-4, Maylard Incision).

Hesselbach triangle is the region in the anterior abdominal wall bounded inferiorly by the inguinal ligament, medially by the lateral border of the rectus muscles, and laterally by the inferior epigastric vessels (see Fig. 38-3). Direct hernias protrude through the abdominal wall in Hesselbach triangle, as opposed to indirect hernias that do so through the deep ring lying lateral to this triangle.

Nerve Supply

The anterior abdominal wall is innervated by the abdominal extensions of the intercostal nerves (T7-11), the subcostal nerve (T12), and the iliohypogastric and the ilioinguinal nerves (L1). The T10 dermatome approximates the level of the umbilicus.

The *iliohypogastric nerve* provides sensation to the skin over the suprapubic area. The *ilioinguinal nerve* supplies the skin of the lower abdominal wall and upper portion of the labia majora and medial portion of the thigh (see Fig. 38-4). These two nerves pass 2 to 3 cm medial to the anterosuperior iliac spine and course between the layers of the rectus sheath (see Fig. 38-2) (Whiteside, 2003).

CLINICAL CORRELATION

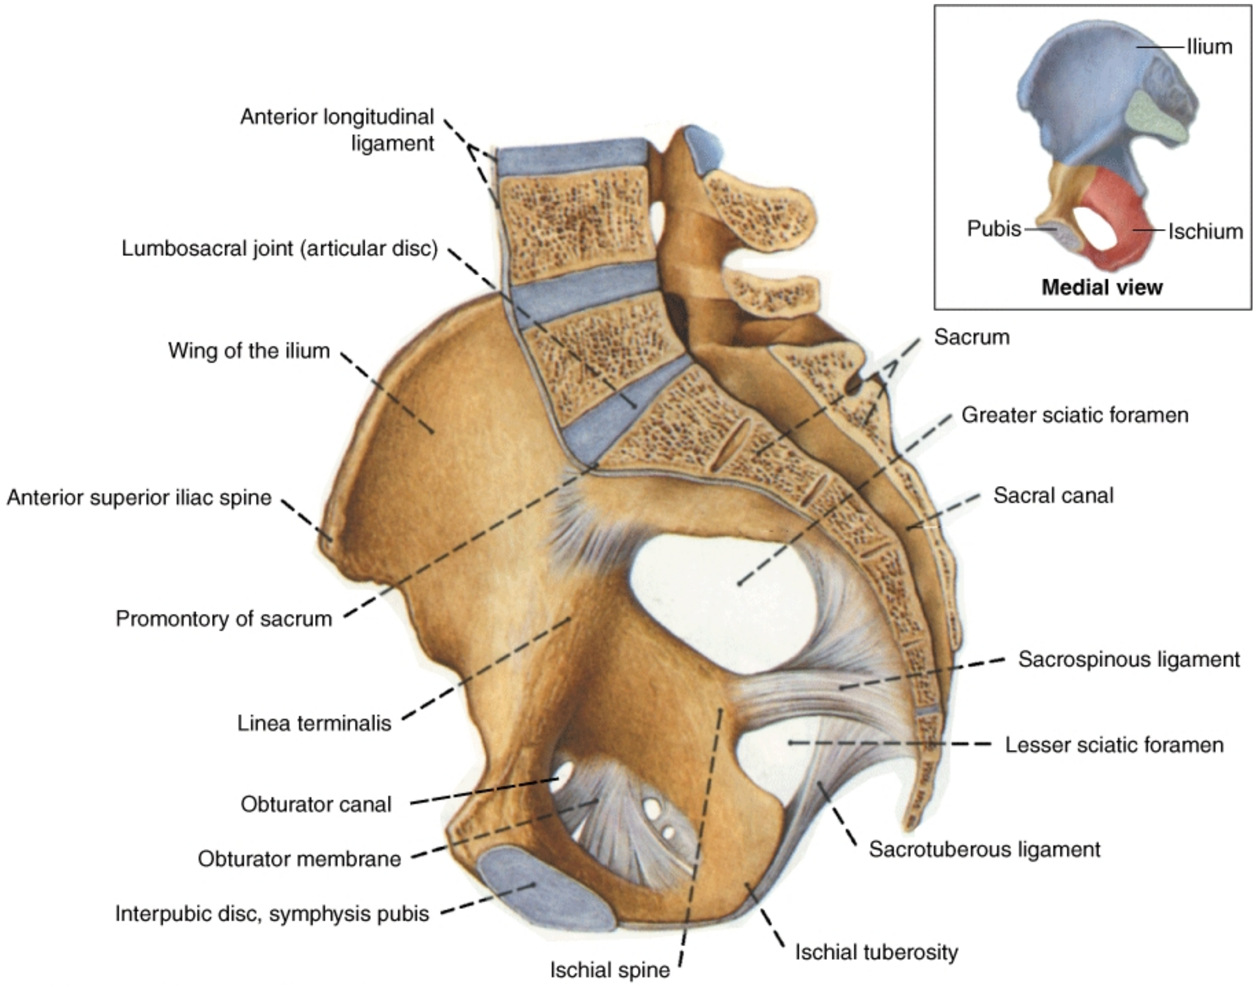
The ilioinguinal and iliohypogastric nerves can be severed during abdominal entry or entrapped during closure with low transverse incisions. This is especially true if incisions extend beyond the lateral borders of the rectus muscle. They also may be injured by placement of lower abdominal accessory trocars during laparoscopy. Most women with injury to these nerves present with loss of sensory function in the areas of distribution, however chronic pain can result (see Chap. 11, Neurologic).

PELVIC ANATOMY

Bony Pelvis and Pelvic Joints

The bony pelvis is comprised of (1) the two hip bones, termed the *inominate bones;* (2) the sacrum; and (3) the coccyx (Fig. 38-5). The innominate bones consist of the ilium, ischium, and pubis, which fuse at the acetabulum, a cup-shaped structure that articulates with the femoral head. The ilium articulates with the sacrum posteriorly at the sacroiliac joint, and the pubic bones articulate with each other anteriorly at the symphysis pubis. The s*acroiliac joint* is a synovial joint that connects the articular surfaces of the sacrum and ilium. This joint and its ligaments contribute significantly to the stability of the bony pelvis. The *symphysis pubis* is a cartilaginous joint that connects the articular surfaces of the pubic bones by way of a fibrocartilaginous disk. The ischial spines are clinically important bony prominences that project posteromedially from the medial surface of the ischium approximately at the level of the fifth sacral vertebra (S5).

FIGURE 38-5



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Hemisected female pelvis. *Inset:* Bones of the pelvis. *(From Clemente, 1997, and McKinley, 2006, with permission.)*

Pelvic Openings

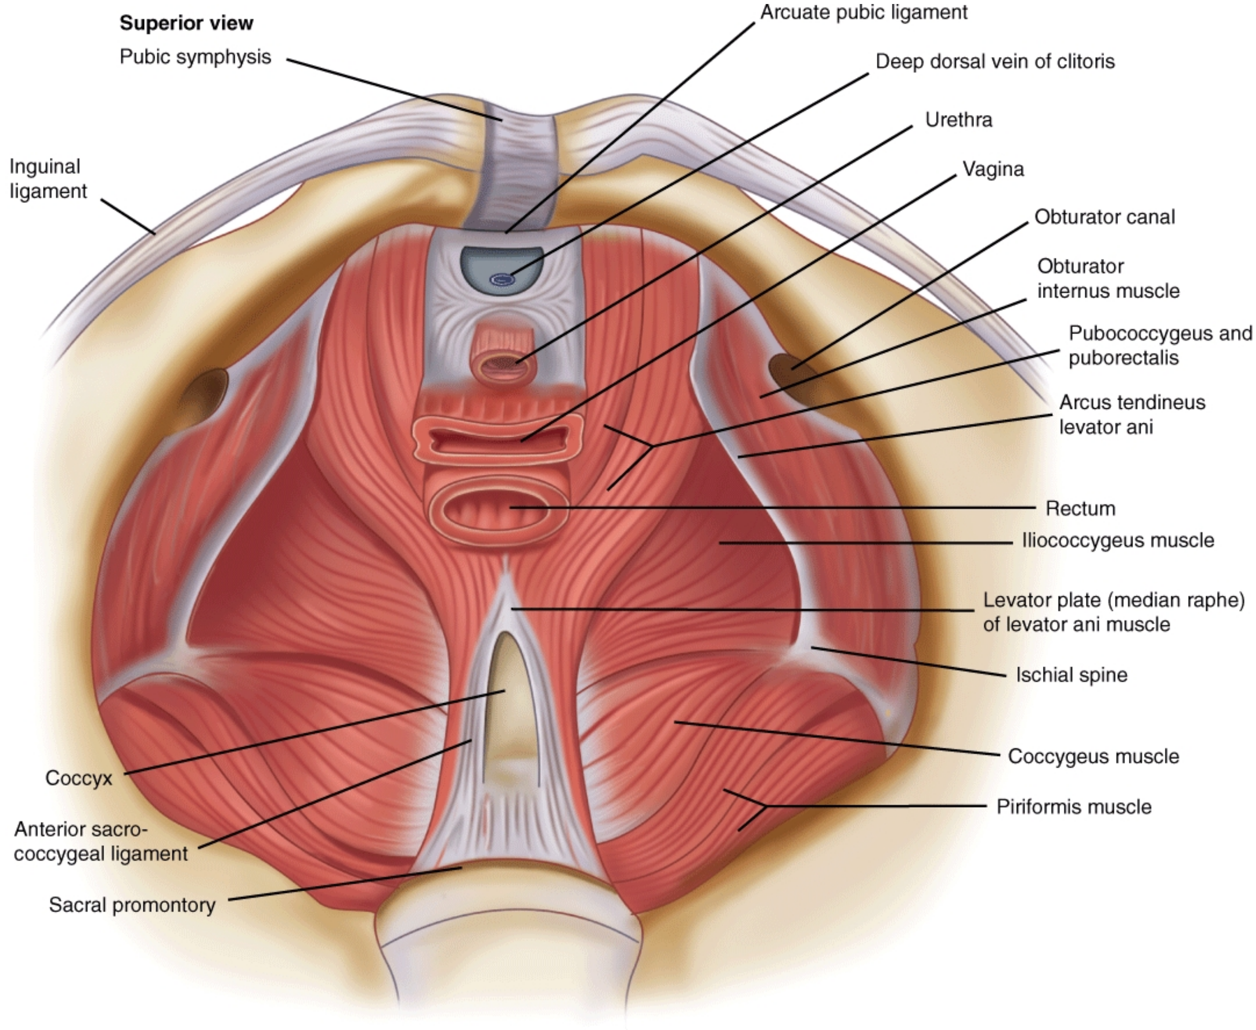
The posterior, lateral, and inferior walls of the pelvis have several openings through which many important structures pass. The large *obturator foramen* between the ischium and pubis is filled almost completely by the obturator membrane (see Fig. 38-5). In the superior portion of this membrane, a small aperture known as the *obturator canal* allows passage of the obturator neurovascular bundle into the medial (adductor) compartment of the thigh.

The posterolateral walls of the pelvis are not covered by bone. Instead, two important accessory ligaments, the sacrospinous and sacrotuberous, divide the greater and lesser sciatic notches of the ischium into the *greater sciatic foramen and lesser sciatic foramen* (see Fig. 38-5). The piriformis muscle, internal pudendal and inferior gluteal vessels, sciatic nerve, and other branches of the sacral nerve plexus pass through the greater sciatic foramen in close proximity to the ischial spines. The internal pudendal vessels, pudendal nerve, and obturator internus tendon pass through the lesser sciatic foramen.

Posteriorly, there are four pairs of pelvic sacral foramina. These allow passage of the anterior divisions of the first four sacral nerves and lateral sacral arteries and veins.

Lastly, the *urogenital hiatus* is the U-shaped opening in the pelvic floor muscles. Through it the urethra, vagina, and rectum pass (Fig. 38-6).

FIGURE 38-6



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Superior view of pelvic floor muscles. *(From Netter, 1989, with permission.)*

CLINICAL CORRELATION

Anatomic knowledge of the greater sciatic foramen area is critical to avoid neurovascular injury during sacrospinous fixation procedures and when administering pudendal nerve blockade. Weakening and opening of the urogenital hiatus from neuromuscular injury to pelvic floor muscles allows urogenital prolapse, as described below.

Ligaments

The term *ligament* is most often used to describe dense connective tissue that connects two bones. However, the ligaments of the pelvis are variable in composition and function. They range from tough connective tissue structures that support the bony pelvis and pelvic organs to smooth muscle and loose areolar tissue that add no significant support. *Of these the Sacrospinous ligament, sacrotuberous ligament,* and *anterior longitudinal ligament of the sacrum* consist of dense connective tissue that joins bony structures and contribute to the stability of the bony pelvis.

CLINICAL CORRELATION

The sacrospinous and anterior longitudinal ligaments serve as suture fixation sites in suspensory procedures used to correct pelvic

organ prolapse. The iliopectineal ligament, also termed *Cooper ligament,* is a thickening in the periosteum of the pubic bone that is often used to anchor sutures in retropubic bladder neck suspension procedures.

The round and broad ligaments consist of smooth muscle and loose areolar tissue, respectively. Although they connect the uterus and adnexa to the pelvic walls, they do not contribute to the support of these organs. In contrast, the cardinal and uterosacral ligaments do aid in pelvic organ support and are discussed later (Uterine Support).

Pelvic Wall Muscles and Fascia

MUSCLES

The posterior, lateral, and inferior walls of the pelvis are partially covered by striated muscles and their investing layers of fasciae (Fig. 38-6). The *piriformis muscle* arises from the anterior and lateral surfaces of the sacrum and partially fills the posterolateral pelvic walls. It exits the pelvis through the greater sciatic foramen, attaches to the greater trocanter of the femur, and functions as an external or lateral hip rotator. The *obturator internus muscle* partially fills the sidewalls of the pelvis. This muscle arises from the pelvic surfaces of the ilium and ischium, as well as from the obturator membrane. It exits the pelvis through the lesser sciatic foramen, attaches to the greater trochanter of the femur, and also functions as an external hip rotator.

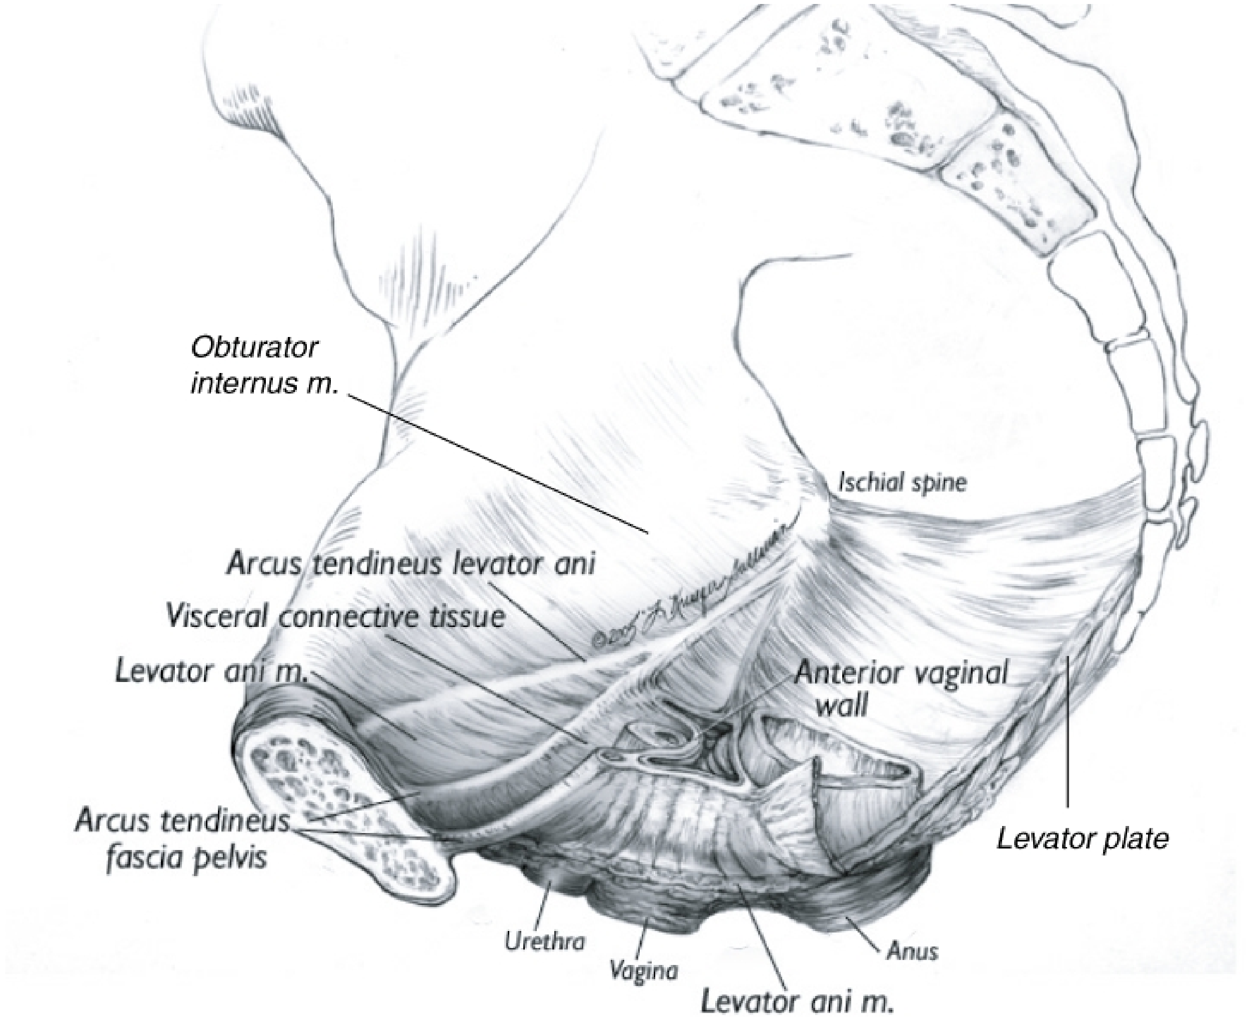
Clinical Correlation

Stretch injury to the piriformis muscle may cause persistent hip pain that can be confused with other hip or pelvic pathology.

FASCIA

The fascia that invests striated muscles is termed *parietal fascia* . Histologically, this tissue consists of regular arrangements of collagen. Pelvic parietal fascia provides muscle attachment to the bony pelvis and serves as anchoring points for visceral fascia, also termed *endopelvic fascia* . Shown in Figure 38-7 is the *arcus tendineus levator ani* , a condensation of fascia covering the medial surface of the obturator internus muscle. This structure serves as the point of origin for parts of the very important levator ani muscles. Also shown is the *arcus tendineus fascia pelvis* , a condensation of fascia covering the medial aspect of the obturator internus and levator ani muscles. It represents the lateral point of attachment of the anterior vaginal wall.

FIGURE 38-7



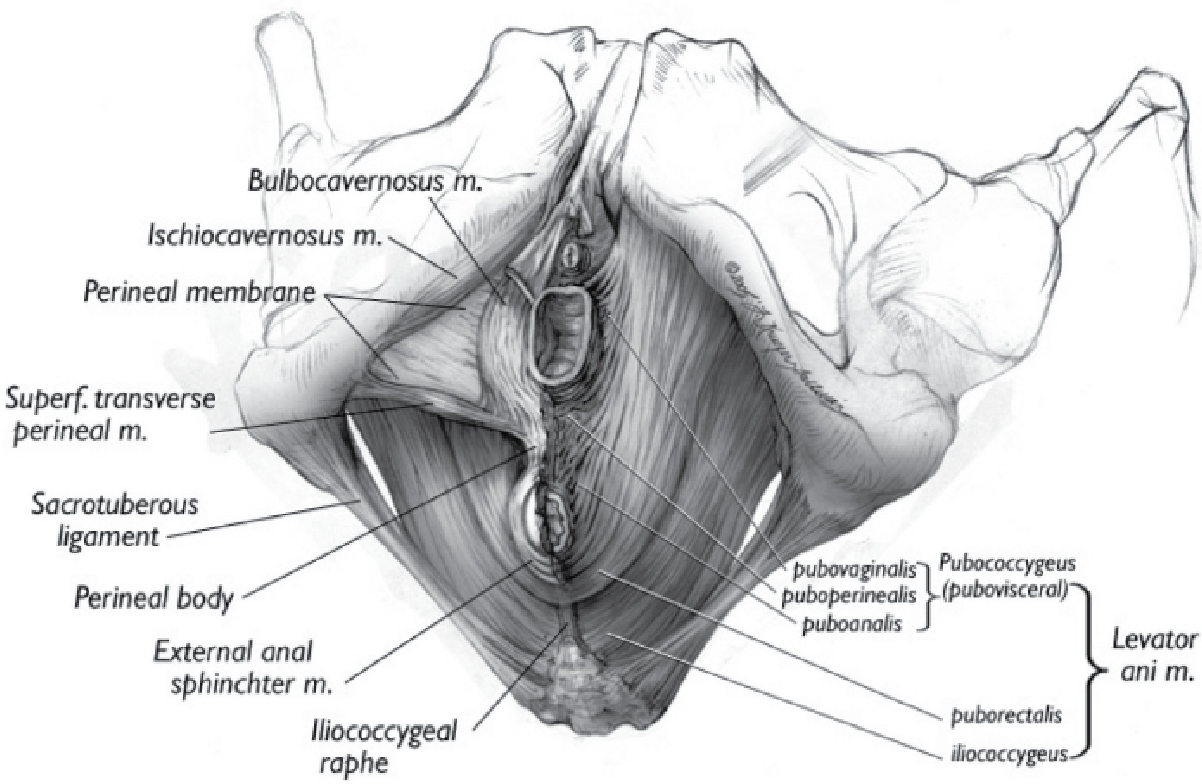
Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

View of lateral pelvic sidewall.

Pelvic Floor

The muscles that span the pelvic floor are collectively known as the *pelvic diaphragm* (Fig. 38-8). This diaphragm consists of the levator ani and coccygeus muscles along with their superior and inferior investing layers of fasciae. Inferior to the pelvic diaphragm, the perineal membrane and perineal body also contribute to the pelvic floor.

FIGURE 38-8



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Inferior view of pelvic floor muscles.

LEVATOR ANI MUSCLES

This is the most important muscle in the pelvic floor and represents a critical component of pelvic organ support (see Figs. 38-6 and 38-8). Physiologically, normal levator ani muscles maintain a constant state of contraction. They provide a solid floor that supports the weight of the abdominopelvic contents against intra-abdominal forces.

The levator ani muscle is a complex unit that consists of several muscle components with different origins and insertions and therefore different functions. The *pubococcygeus, puborectalis,* and *iliococcygeus* are the three components of this muscle recognized in the *Terminologia Anatomica* (see Fig. 38-8). The pubococcygeus is further divided into the pubovaginalis, puboperinealis, and puboanalis muscles according to fiber attachments. Because of the significant attachments of the pubococcygeus to the walls of the pelvic viscera, the term *pubovisceral muscle* is used frequently to describe this portion of the levator ani muscle (Kerney, 2004, Lawson, 1974).

Pubococcygeus Muscle

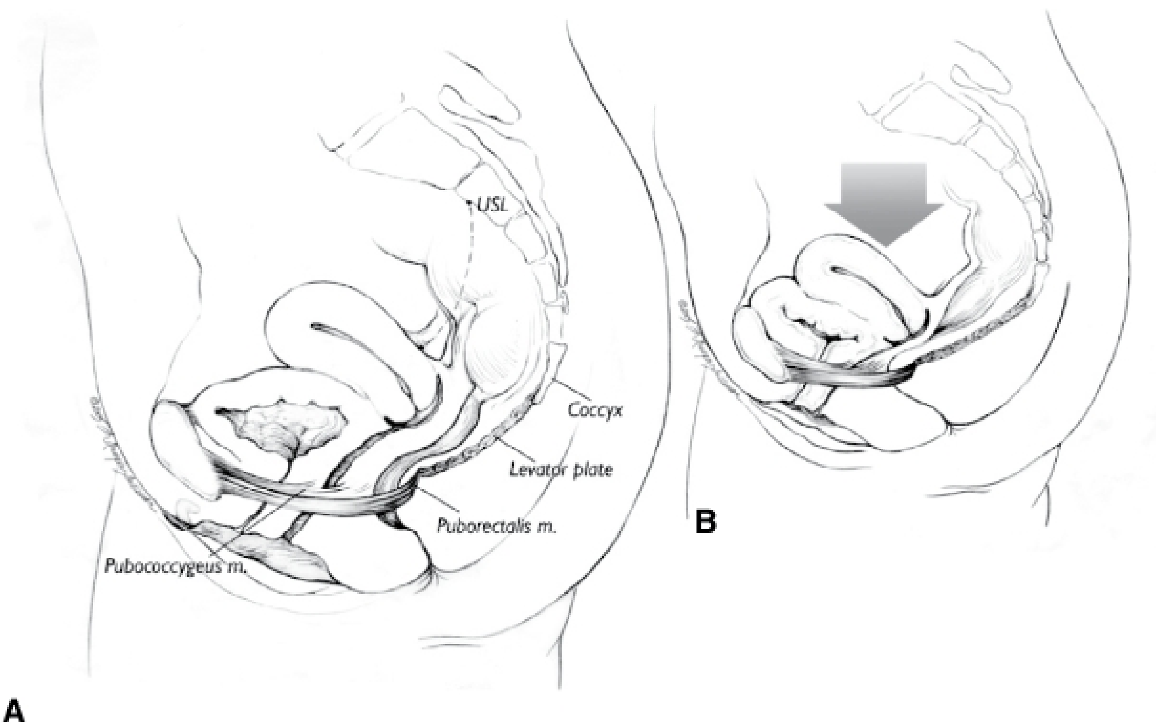
The anterior ends of the pubococcygeus (pubovisceral muscle) arise on either side from the inner surface of the pubic bone (see Fig. 38-8). The *pubovaginalis* refers to the medial fibers that attach to the lateral walls of the vagina. Although there are no direct attachments of the levator ani muscles to the urethra in females, those fibers of the muscle that attach to the vagina are responsible for elevating the urethra during a pelvic muscle contraction. Hence, these may contribute to urinary continence (DeLancey, 1990). The *puboperinealis* refers to the fibers that attach to the perineal body and draw this structure toward the pubic

symphysis. The *puboanalis* refers to the fibers that attach to the anus at the intersphincteric groove between the internal and external anal sphincters. These fibers elevate the anus and, along with the rest of the pubococcygeus and puborectalis fibers, keep the urogenital hiatus narrowed.

Puborectalis Muscle

The puborectalis represents the medial and inferior fibers of the levator ani muscle that arise on either side from the pubic bone and form a U-shaped sling behind the anorectal junction (Fig. 38-9). The action of the puborectalis draws the anorectal junction toward the pubis, contributing to the anorectal angle. This muscle is considered part of the anal sphincter complex and may contribute to maintenance of fecal continence (see Chap. 25, Anal Sphincter Complex).

FIGURE 38-9



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

A. Pelvic organs and pelvic floor muscles. **B.** With increasing intra-abdominal pressure, the muscles of the pelvic floor contract to support pelvic viscera.

Iliococcygeus Muscle

The iliococcygeus, the most posterior and thinnest part of the levator ani muscles, has a primarily supportive role. It arises laterally from the arcus tendineous levator ani and the ischial spines. Muscle fibers from one side join those from the opposite side at the coccyx and the iliococcygeal raphe, also termed the *anococcygeal raphe* (see Fig. 38-8).

The *levator plate* is the clinical term used to describe the region between the anus and the coccyx formed primarily by the insertion of the iliococcygeus muscles (see Figs. 38-7 and 38-9). This portion of the levator muscles forms a supportive shelf on which the rectum, upper vagina, and uterus rest.

In a woman with normal support, the levator plate lies almost parallel to the horizontal plane in the standing position (Berglas, 1953). One theory suggests that levator plate support prevents excessive tension or stretching of the connective tissue pelvic ligaments and faciae (Paramore, 1908). Accordingly, neuromuscular injury to the levator muscles may lead to eventual sagging or

vertical inclination of the levator plate and of the urogenital hiatus. Consequently, the vaginal axis becomes more vertical, and the cervix is oriented over the opened hiatus. The mechanical effect of this change is to increase strain on connective tissues that support the pelvic viscera. Increased urogenital hiatus size has been shown to correlate with increased severity of pelvic organ prolapse (DeLancey, 1998).

PELVIC FLOOR INNERVATION

The pelvic diaphragm muscles are innervated primarily by direct somatic efferents from the second through the fifth sacral nerve roots (S2-5). Traditionally, a dual innervation has been described. The pelvic or superior surface of the muscles is supplied by direct efferents from S2-5, which is the nerve to the levator ani muscle.

The perineal or inferior surface is supplied by branches of the pudendal nerve. This latter relationship has been challenged recently. It has been suggested that the pudendal nerve does not contribute to levator muscle innervation (Barber, 2002). Its branches do, however, innervate parts of the striated urethral sphincter and external anal sphincter muscles.

Separate innervation of the levator ani muscle and the striated urethral and anal sphincters may explain why some women develop pelvic organ prolapse and others develop urinary or fecal incontinence (Heit, 1996).

PELVIC CONNECTIVE TISSUE

Subperitoneal perivascular connective tissue and loose areolar tissue are found throughout the pelvis. This tissue connects the pelvic viscera to the pelvic walls and is termed *visceral* or *endopelvic fascia.* Recall that visceral fascia differs anatomically and histologically from parietal fascia, which invests most striated muscles (Table 38-1). Visceral fascia is intimately associated with the walls of the viscera and cannot be dissected in the same fashion as parietal fasciaâ€”for example, rectus fascia can be separated from its corresponding skeletal muscle.

Table 38-1 Differences between Visceral and Parietal Fascia of the Pelvic Floor Muscles

	Type of Fascia	
Characteristic	**Visceral or Endopelvic**	**Parietal**
Histologic	Loose arrangements of collagen, elastin, and adipose tissue	Organized collagen arrangements
Function	Allows expansion and contraction of invested structures	Provides muscle attachment to bones
Supportive role	Condensations lend some support to invested organs; encases neurovascular structures	Invests muscles to provide pelvic floor stability and function
Tensile strength	Elastic	Rigid

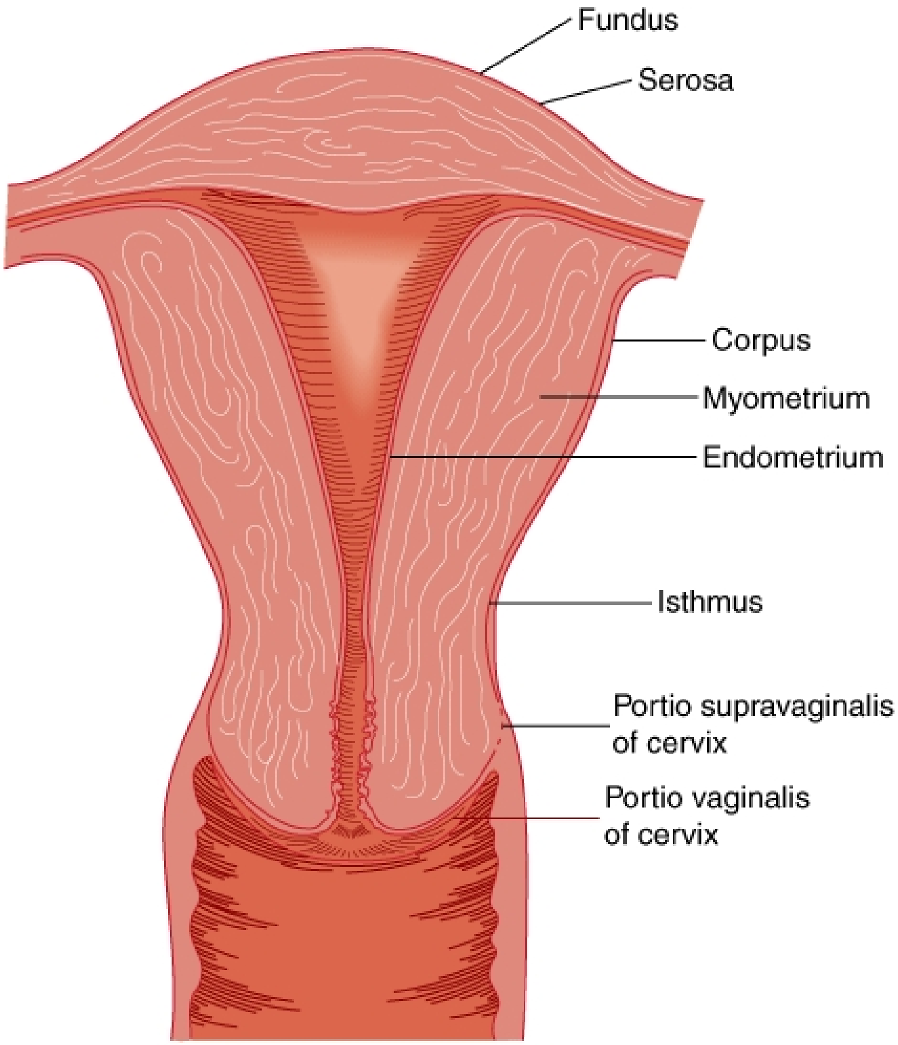
Condensations of visceral connective tissue that have assumed special supportive roles have been given different names. Some examples include the cardinal and uterosacral ligaments and the vesicovaginal and rectovaginal fasciae. These will be described further in sections below.

Pelvic Viscera

UTERUS

The uterus is a fibromuscular hollow organ situated between the bladder and the rectum. The uterus is divided structurally and functionally into two portions: an upper muscular body, the *corpus* , and a lower fibrous *cervix* (Fig. 38-10). The portion of the corpus that extends above the level of entry of the fallopian tubes into the endometrial cavity is known as the *fundus* .

FIGURE 38-10



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterine anatomy.

The shape, weight, and dimensions of the uterus vary according to parity and estrogen stimulation. Before menarche and after menopause, the corpus and cervix are approximately equal in size, but during the reproductive years, the uterine corpus is significantly larger. In the adult, nonpregnant woman, the uterus measures approximately 7 cm in length and 5 cm in width at the fundus and weighs 30 to 40 g. The embryologic development of the uterus and other pelvic viscera is discussed in Chapter 18.

Endometrium and Serosa

The uterus consists of an inner layer of mucosa called the *endometrium* that surrounds the endometrial cavity and a thick muscular wall known as the *myometrium.* The endometrium consists of columnar epithelium and specialized stroma. The superficial portion of the endometrium undergoes cyclic changes with the menstrual cycle (see Figs. 15-18 and 15-24).

The spiral arterioles located in the endometrium undergo hormonally mediated constriction or spasms that cause shedding of the superficial portion of this layer with each menstrual cycle. Because different arteries supply the deeper basal layer of the endometrium, this layer is preserved after the menstrual cycle and is the one responsible for regeneration of a new layer in the

subsequent cycle (see Fig. 8-2).

Peritoneal serosa overlays the outer wall except for the anterior portion of the cervix, which is covered by the bladder, and for the lateral portions of the corpus and cervix that attach to ligaments, as discussed below.

Cervix

The uterine cervix begins caudal to the uterine isthmus and is approximately 2 cm in length. The wall of the cervix consists primarily of fibrous tissue and a smaller amount (approximately 10 percent) of smooth muscle. The smooth muscle is found on the periphery of the cervical wall and serves as the point of attachment for the cardinal and uterosacral ligaments and for the fibromuscular walls of the vagina.

The attachments of the vaginal walls to the periphery of the cervix divides it vertically into a vaginal part known as the *portio vaginalis* and a supravaginal part known as the *portio supravaginalis.* The portio vaginalis is covered by nonkeratinizing squamous epithelium (see Fig. 38-10).

The endocervical canal is lined by columnar, mucus-secreting epithelium. The lower border of the canal, called the *external cervical* os, contains a transition from squamous epithelium of the portio vaginalis to columnar epithelium of the cervical canal (see Fig. 29-2). The exact location of this transition, termed the *squamocolumnar junction* and also called the *transformation zone* , varies depending on hormonal status. At the upper border of the endocervical canal is the internal cervical os, where the narrow cervical canal becomes continuous with the wider endometrial cavity.

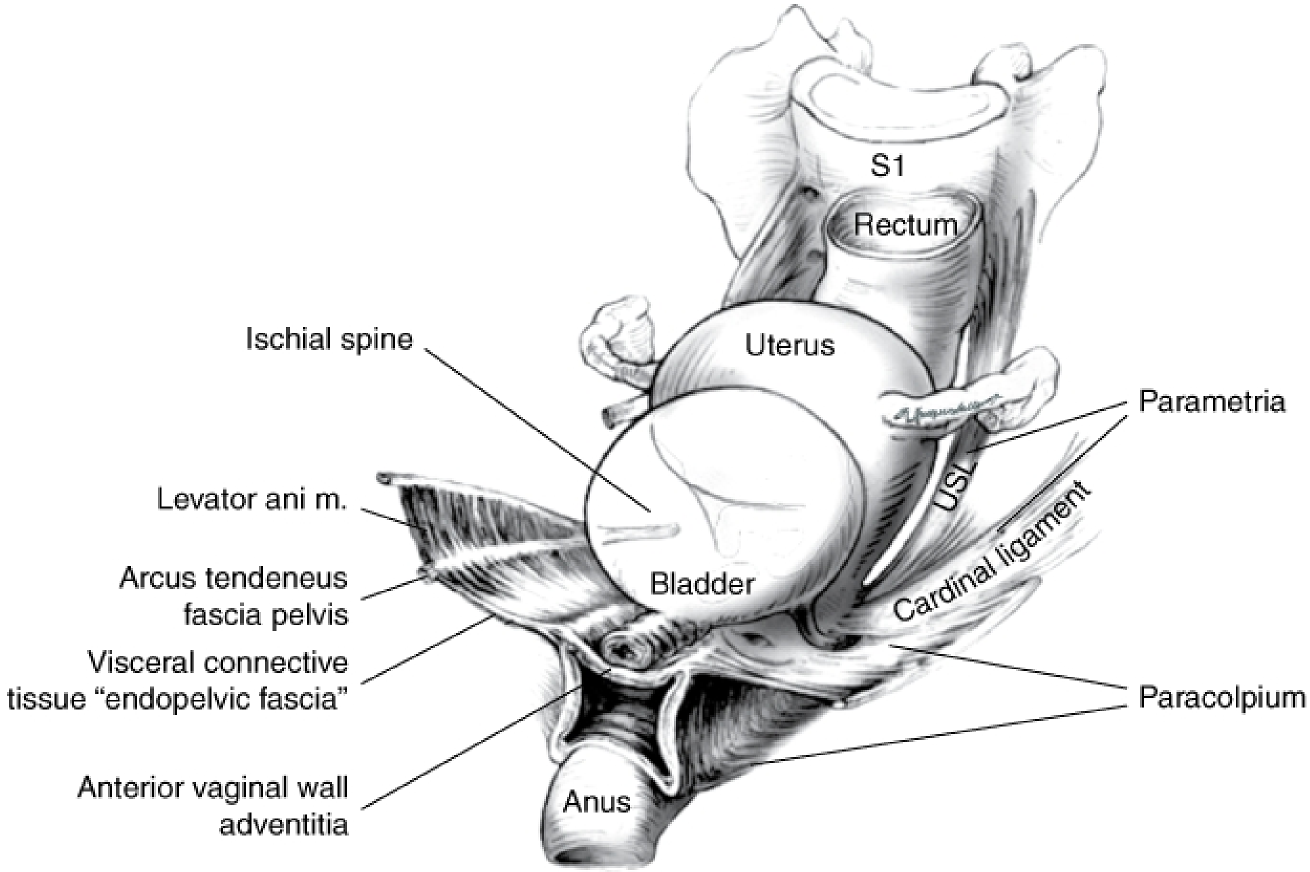
Clinical Correlation

Most squamous epithelial neoplasias originate at the squamocolumar junction. Thus, correct PAP smear preparation should sample cells from this junction, as discussed in Chapter 29, Cervical Cytology.

Uterine Support

The main support of the uterus and cervix is provided by the interaction between the levator ani muscles and the connective tissue that attaches the walls of the cervix to the pelvic walls. The connective tissue that attaches lateral to the uterus is called the *parametria.* It consists of what is known clinically as the *cardinal ligament* and *uterosacral ligament* (Figs. 38-11 and 38-12).

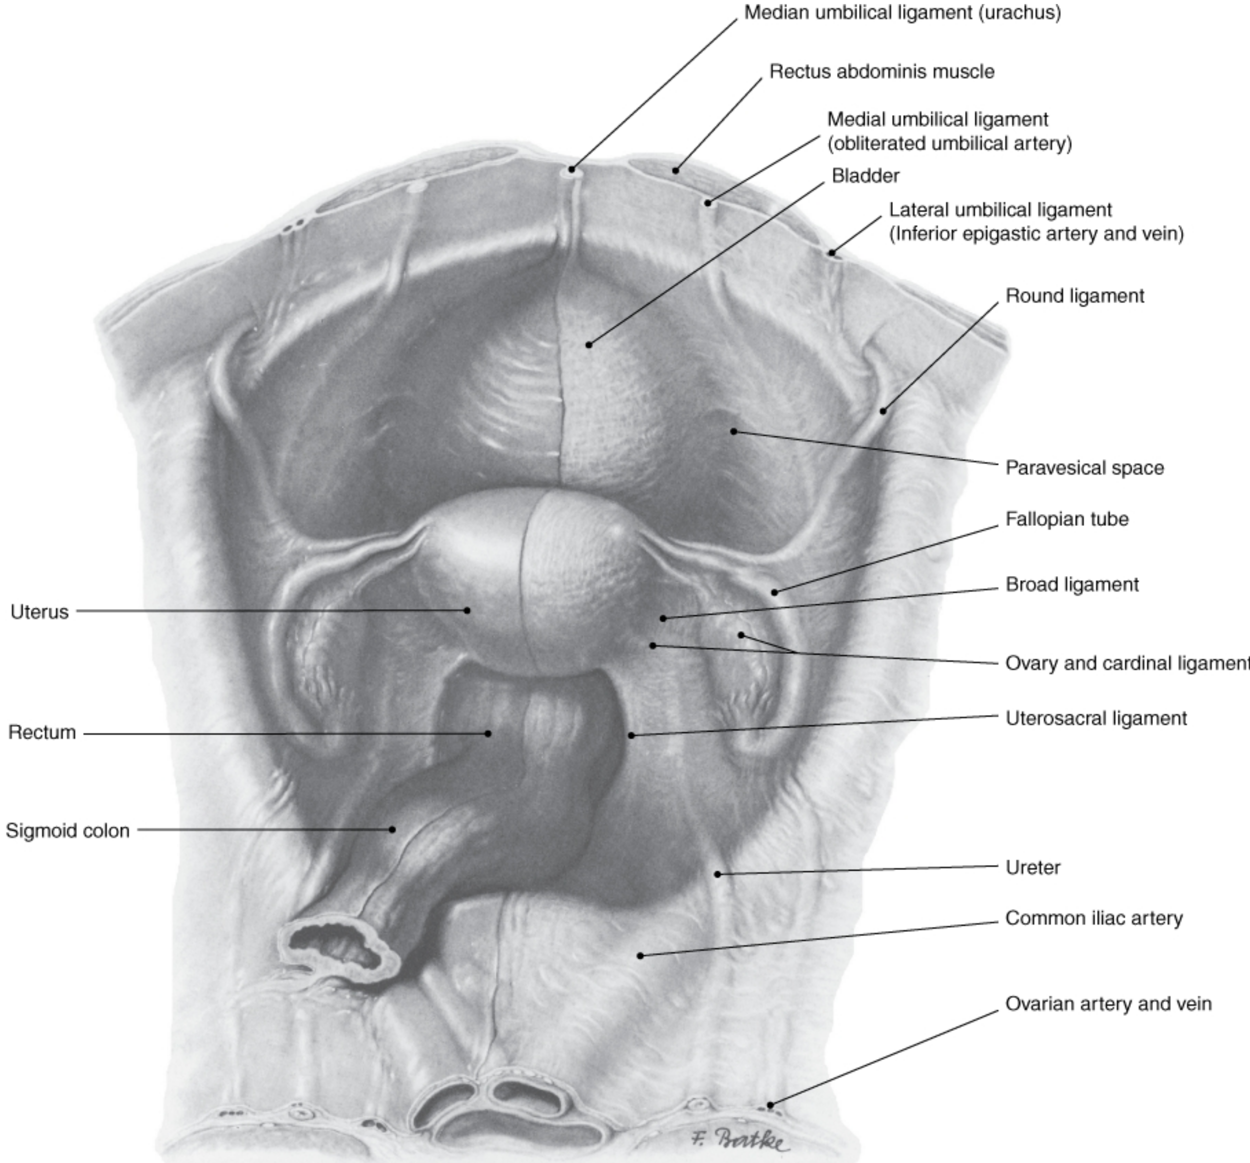
FIGURE 38-11



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pelvic viscera and their support.

FIGURE 38-12



Major pelvic organs and associated anatomy. *(From Reiffenstuhl, 1975, with permission.)*

These ligaments are condensations of visceral connective tissue that have assumed special supportive roles. The cardinal ligaments, also termed *transverse cervical ligaments* or *Mackenrodt ligaments,* consist primarily of perivascular connective tissue (Range, 1964). They attach to the posterolateral pelvic walls near the origin of the internal iliac artery and surround the vessels supplying the uterus and vagina.

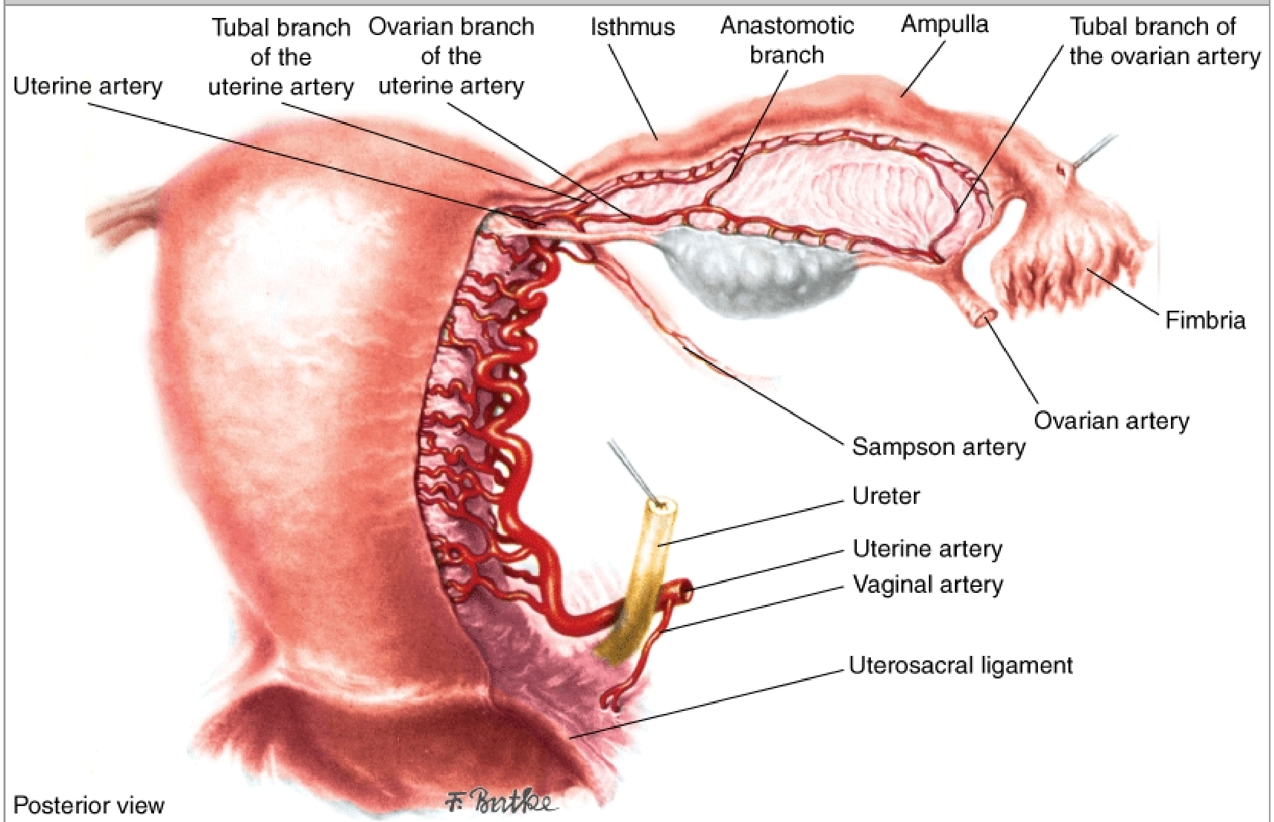
The uterosacral ligaments attach to a broad area of the sacrum posteriorly and form the lateral boundaries of the posterior cul-de-sac of Douglas (see Figs. 38-11 and 38-12). They consist primarily of smooth muscle and contain some of the pelvic autonomic nerves (Campbell, 1950). The parametria continues down along the vagina as the *paracolpium* , which is described below.

Round Ligaments

The *round ligaments* of the uterus are smooth muscle extensions of the uterine corpus and represent the homologue of the gubernaculum testis. The round ligaments arise from the lateral aspect of the corpus just below and anterior to the origin of the

fallopian tubes. They extend laterally to the pelvic sidewall (see Fig. 38-12). They enter the retroperitoneal space and pass lateral to the inferior epigastric vessels before entering the inguinal canal through the internal inguinal ring (see Fig. 38-4). After coursing through the inguinal canal, the round ligaments exit through the external inguinal ring to terminate in the subcutaneous tissue of the labia majora. The round ligaments do not contribute significantly to uterine support. They receive their blood supply from a small branch of the uterine or ovarian artery known as *Sampson artery* (Fig. 38-13).

FIGURE 38-13



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Uterine and adnexal blood supply. *(From Reiffenstuhl, 1975, with permission.)*

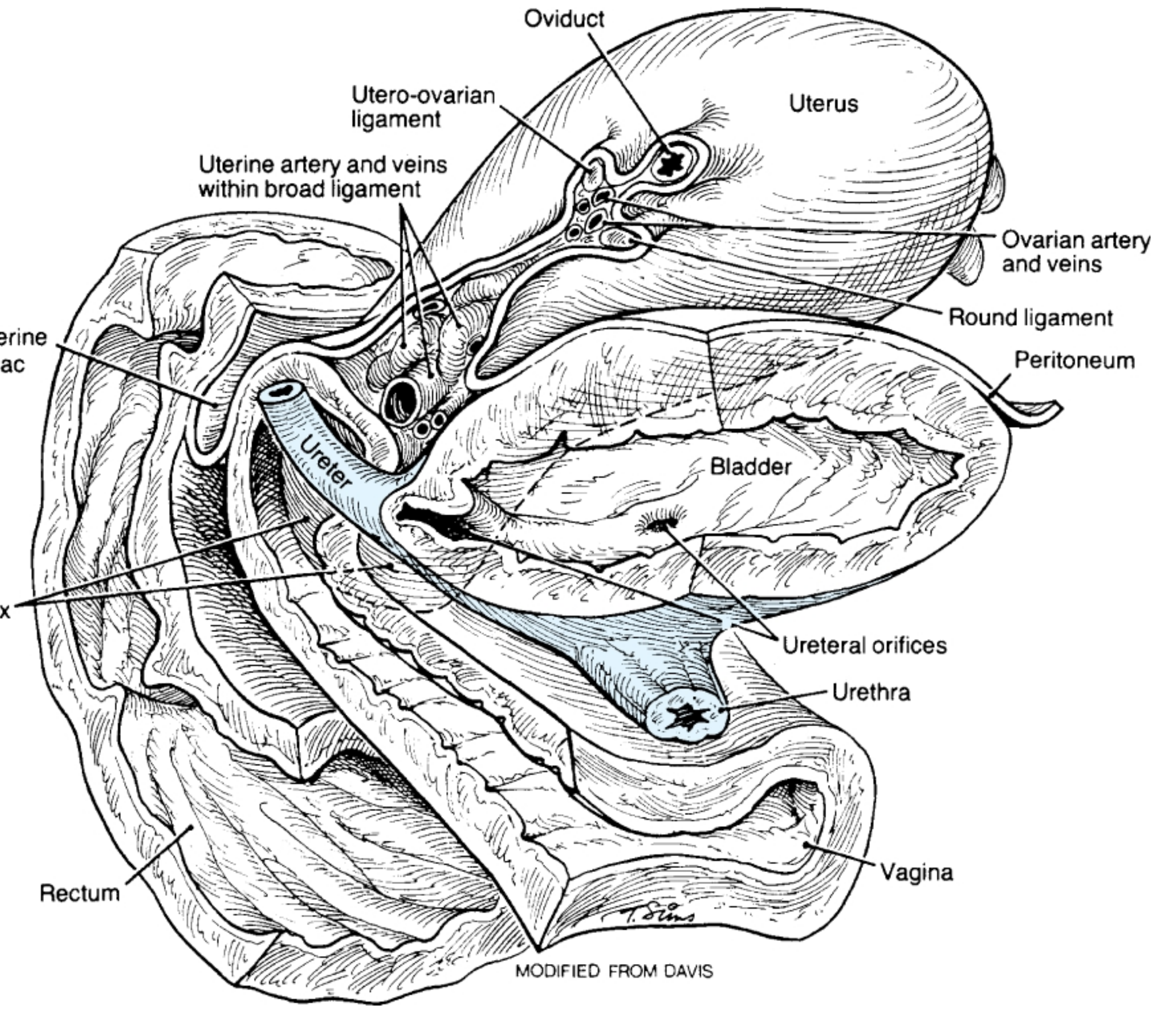
Clinical Correlation

The location of the round ligament anterior to the fallopian tube can assist a surgeon during tubal sterilization through a minilaparotomy incision. This may be especially true if pelvic adhesions limit tubal mobility and thus indentification of fimbria prior to tubal ligation.

Broad Ligaments

The broad ligaments are double layers of peritoneum that extend from the lateral walls of the uterus to the pelvic walls (Fig. 38-14). Within the upper portion of these two layers lie the fallopian tubes and the ovarian and round ligaments. The fallopian tubes, ovaries, and round ligaments each have their separate mesentery, called the *mesosalpinx, mesovarium,* and *mesoteres,* respectively, that carries nerves and vessels to these structures. At the lateral border of the fallopian tube and the ovary, the broad ligament ends where the infundibulopelvic ligament blends with the pelvic wall (see Fig. 38-12). The cardinal and uterosacral ligaments lie within the lower portion of the broad ligaments.

FIGURE 38-14

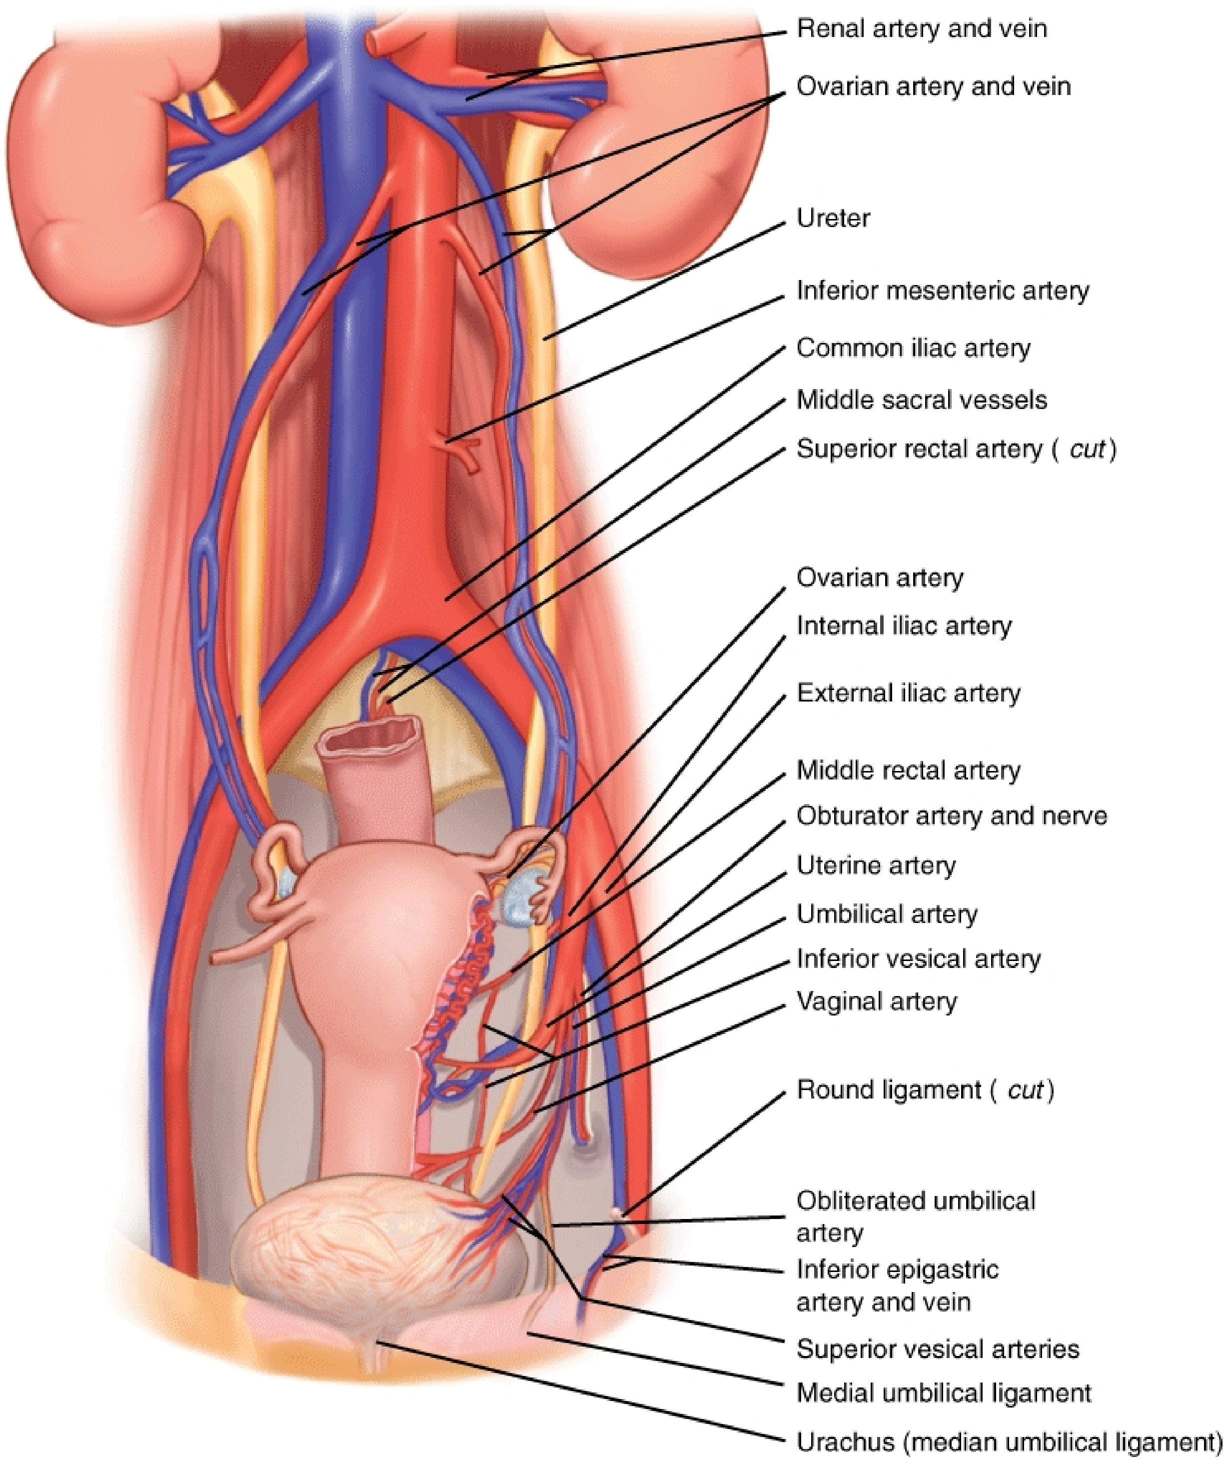


Sagittal section through the uterine end of the broad ligament. *(From Cunningham, 2005, with permission.)*

Uterine Blood Supply

The blood supply to the uterine corpus arises from the ascending branch of the *uterine artery* and from the medial or uterine branch of the *ovarian artery* (Fig. 38-15; see also Fig. 38-13). The uterine artery may originate directly from the internal iliac artery as an independent branch, or it may have a common origin with the internal pudendal or vaginal artery.

FIGURE 38-15



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Course of the ureter and blood supply to the pelvic organs. *(From Netter, 1989, with permission.)*

The uterine artery approaches the uterus in the area of transition between the corpus and the cervix known as the *uterine isthmus*

(see Figs. 38-10 and 38-13). In this area, the uterine artery courses over the ureter and provides a small branch to this structure. Several uterine veins course along the side of the artery and are variably found over or under the ureter. The uterine artery then divides into a larger ascending and a smaller descending branch that course along the side of the uterus and cervix. These vessels connect on the lateral border of the uterus and form an anastomotic arterial arcade that supplies the uterine walls.

The cervix is supplied by the descending or cervical branch of the uterine artery and by ascending branches of the vaginal artery.

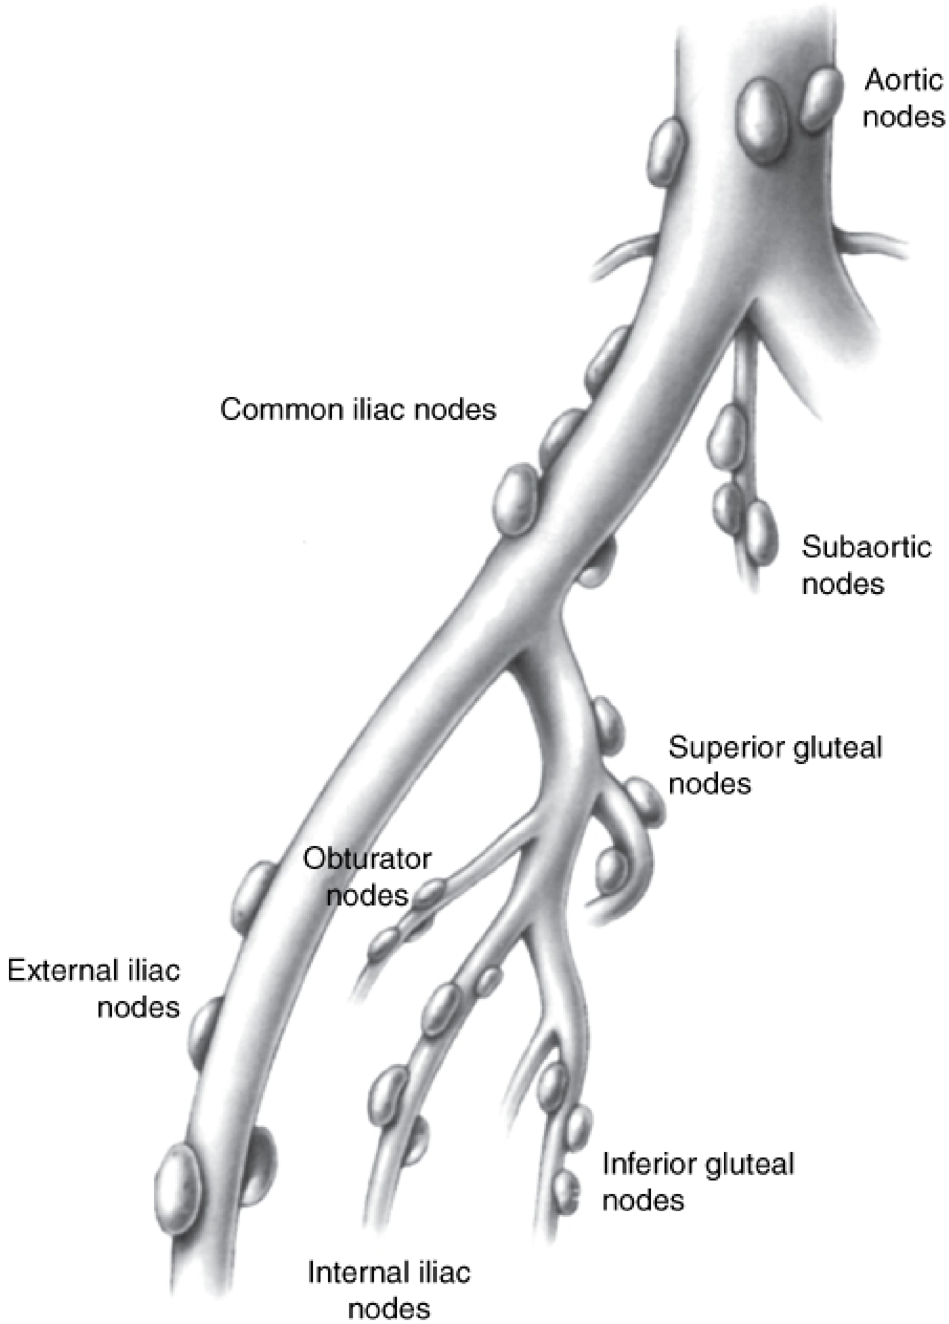
Clinical Correlation

The uterus receives dual blood supply from both ovarian and uterine vessels. For this reason, some surgeons during myomectomy place tourniquets at both the infundibulopelvic ligament and the uterine isthmus to decrease blood flow from the ovarian and uterine arteries, respectively.

Uterine Lymphatic Drainage

Lymphatic drainage of the uterus is primarily to the obturator and internal and external iliac nodes (Fig. 38-16). However, some lymphatic channels from the uterine corpus may pass along the round ligaments to the superficial inguinal nodes (see Fig. 38-4), and others may extend along the uterosacral ligaments to the lateral sacral nodes.

FIGURE 38-16



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pelvic lymph nodes. *(From Plentyl, 1971, with permission.)*

Uterine Innervation

The uterus is innervated by fibers of the inferior hypogastric plexus, also known as *Frankenhauser ganglion,* that travel along the uterine arteries and are found in the connective tissue of the cardinal ligaments. Details of the organization of the pelvic visceral innervation are described later (Pelvic Innervation).

OVARIES AND FALLOPIAN TUBES

Ovaries

The ovaries and fallopian tubes constitute the uterine *adnexa* . The size and hormonal activity of the ovaries depend on age, time of the menstrual cycle, and exogenous hormonal suppression. During reproductive years, the ovaries measure 2.5 to 5 cm in length, 1.5 to 3 cm in thickness, and 0.7 to 1.5 cm in width.

Ovaries consist of an outer cortex and an inner medulla. Ovarian cortex is comprised of a specialized stroma punctuated with follicles, corpora lutea, and corpora albicantia. A single layer of mesothelial cells covers this cortex as a surface epithelium. The medullary portion of the ovary consists primarily of fibromuscular tissue and blood vessels. The medial portions of the ovaries are connected to the uterus by the *utero-ovarian ligament* (see Fig. 38-14). Laterally, each ovary is attached to the pelvic wall by an *infundibulopelvic ligament* , also termed *suspensory ligament of the ovary,* that contains the ovarian vessels and nerves (see Fig. 38-12).

Ovarian Blood Supply, Lymphatics, and Innervation

The blood supply to the ovaries comes from the ovarian arteries, which arise from the anterior surface of the abdominal aorta just below the origin of the renal arteries and from the ovarian branches of the uterine arteries (see Figs. 38-13 and 38-15). The ovarian veins follow the same retroperitoneal course as the arteries. The right ovarian vein drains into the inferior vena cava. However, the left ovarian vein drains into the left renal vein.

Lymphatic drainage of the ovaries follows the ovarian vessels to the lower abdominal aorta, where they drain into the para-aortic nodes (see Fig. 38-16).

Innervation to the ovaries are supplied by extensions of the renal plexus that course along the ovarian vessels in the infundibulopelvic ligament.

Fallopian Tubes

The fallopian tubes are tubular structures that measure 7 to 12 cm in length (see Fig. 38-13). Each tube has four identifiable portions. The *interstitial portion* passes through the body of the uterus at the region known as the *cornua.* The *isthmic portion* begins adjacent to the uterine corpus. It consists of a narrow lumen and a thick muscular wall. The *ampullary portion* is recognized as the lumen of the isthmic portion of the tube widens. In addition to a wider lumen, this segment has a more convoluted mucosa. The *fimbriated portion* is the distal continuation of the ampullary segment. The fimbriated end has many frond-like projections that provide a wide surface area for ovum pickup. The *fimbria ovarica* is the projection that is in contact with the ovary.

The ovarian artery runs along the hilum of the ovary and sends several branches through the mesosalpinx to supply the fallopian tubes (see Fig. 38-13). The venous plexus, lymphatic drainage, and nerve supply of the fallopian tubes follow a similar course to that of the ovaries.

VAGINA

The vagina is a hollow viscus whose shape is determined by the structures that surround it and by the attachments of its lateral walls to the pelvic walls, as described below. The distal portion of the vagina is constricted by the action of the levator ani muscles (see Fig. 38-8). Above the pelvic floor, the vaginal lumen is much more capacious and distensible. In the standing or anatomic position, the apex of the vagina is directed posteriorly toward the ischial spines, and the upper two thirds of the vaginal tube lie almost parallel to the horizontal plane of the floor (see Fig 38-9).

Although great variability in length of the vaginal walls is reported, the average length of the anterior vaginal wall is 7 cm, and that of the posterior wall is 9 cm. The shorter distance of the anterior vaginal wall results from the anterior position of the uterine cervix in most women. The recesses within the vaginal lumen in front of and behind the cervix are known as the *anterior fornix* and *posterior fornix,* respectively.

Vaginal Walls

The walls of the vagina consist of three layers. First, adjacent to the lumen, there is a mucosal layer consisting of nonkeratinized squamous epithelium overlying a lamina propia. Below this epithelium, muscular layer is found and consists smooth muscle, collagen, and elastin. Lastly, an adventitial layer consisting of collagen and elastin lies beneath the muscularis (Fig. 38-17; see also

Fig. 24-5). (Weber, 1995, 1997).

A. Complete uterovaginal prolapse. Full-thickness portion of the anterior vaginal wall is resected to display vaginal wall layers. **B.** Anterior vaginal wall layers.

The vagina lies between the bladder and rectum and along with its connections to the pelvic walls provides support to these structures (see Fig. 38-14). The vagina is separated from the bladder and urethra anteriorly and the rectum posteriorly by the vaginal adventitia (see Figs. 38-11 and 38-17). The lateral continuation of the adventitial layer constitutes the paravaginal tissue that attaches the walls of the vagina to the pelvic walls, as described below. This tissue consists of loose areolar and fatty tissue containing blood vessels, lymphatics, and nerves.

The anterior fibromuscular vaginal wall and its paravaginal attachments represent the layer that supports the bladder and urethra. It is referred to clinically as *pubovesicocervical fascia* (see Fig. 38-11). Histologic studies have noted an absence of a true "fascial" layer between the vagina and the bladder and between the vagina and the rectum. Accordingly, some recommend that terms such as *pubocervical/pubovesical fascia* or *rectovaginal fascia* be abandoned. They propose that these are replaced by more accurate descriptive terms such as *vaginal muscularis* or *fibromuscular layer* of the anterior and posterior vaginal walls.

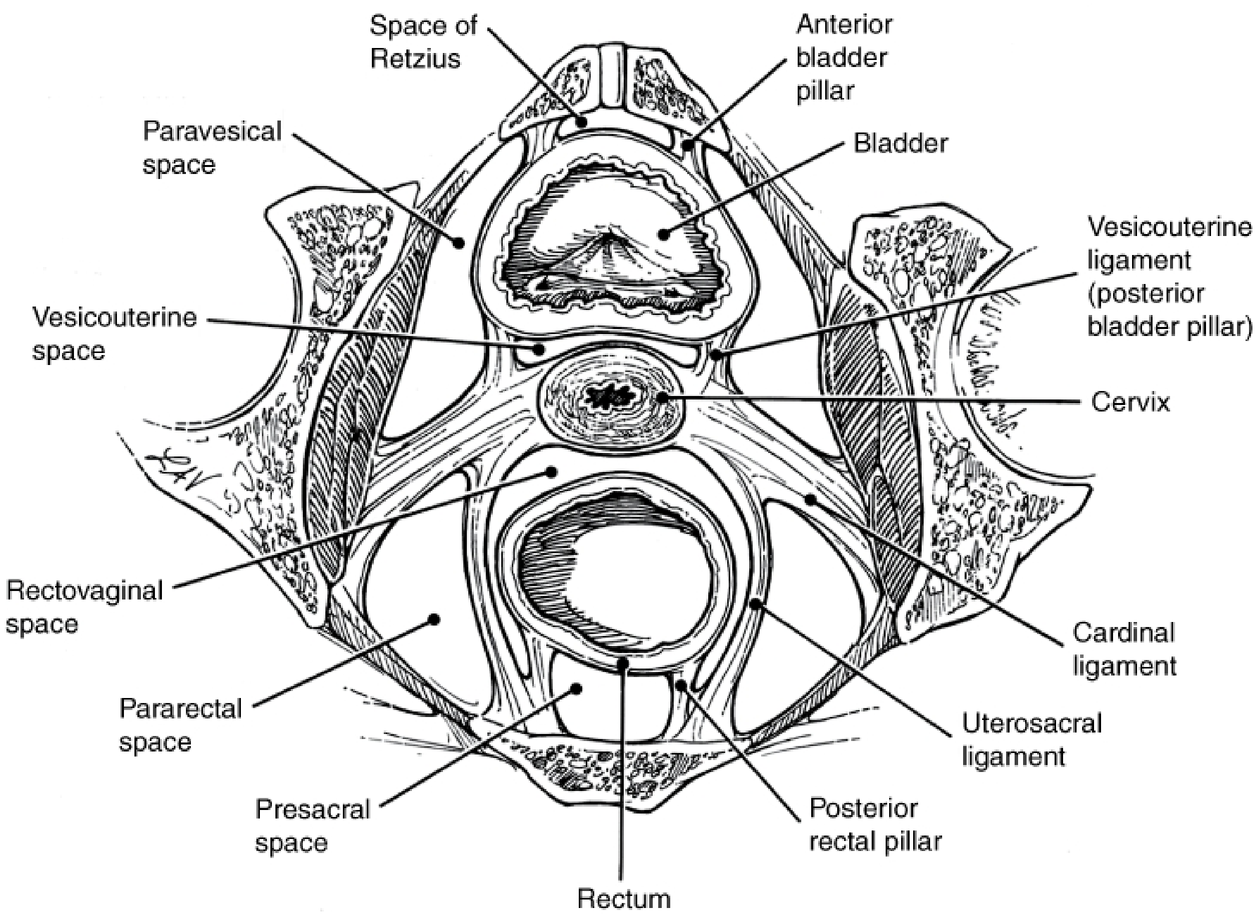
The lateral attachments of the posterior vaginal walls are to the fascia covering the medial surface of the levator ani muscles on the pelvic walls. The posterior wall and its connective tissue attachments to the sidewall support the rectum. This layer is known

clinically as the *rectovaginal fascia* or *fascia of Denonvilliers.* However, similar to microscopic findings of the anterior vaginal wall, histologic studies have failed to show a separate layer between the posterior wall of the vagina and the rectum except in the distal 3 to 4 cm, where the dense fibromuscular tissue of the perineal body separates these structure (DeLancey, 1999). Similar to surgical dissections in the anterior vaginal wall, posteriorly, the plane dissected surgically to separate the vaginal wall from rectum includes portions of the vaginal muscularis.

Vesicocervical and Vesicovaginal "Potential" Spaces

The *vesicocervical space* begins below the vesicouterine peritoneal fold or reflection, which represents the loose attachments of the peritoneum in the region of the anterior cul-de-sac (Fig. 38-18; see also Fig. 38-14). The vesicocervical space continues down as the *vesicovaginal space* , which extends to the junction of the proximal and middle thirds of the urethra. Below this point, the urethra and vagina fuse.

FIGURE 38-18



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Connective tissue and spaces of the pelvis. *(From Nichols, 2000, with permission.)*

Clinical Correlation

The vesicouterine peritoneal fold can be lifted and incised easily to create a bladder flap during an abdominal hysterectomy or cesarean delivery. The distance between the anterior cul-de-sac peritoneum and the anterior vaginal fornix is important during vaginal hysterectomies. This spans several centimeters. Therefore, prior to entering the peritoneal cavity, proper identification and sharp dissection of the loose connective tissue that lies within the vesicovaginal and vesicocervical spaces are necessary (see

Section 41-20, Vaginal Hysterectomy).

Rectovaginal Space

This is adjacent to the posterior surface of the vagina. It extends from the cul-de-sac of Douglas down to the superior border of the perineal body, which extends 2 to 3 cm above the hymeneal ring (see Figs. 38-14 and 38-18). *Rectal pillars* are fibers of the cardinalâ€"uterosacral ligament complex that extend down from the cervix and attach to the upper portion of the posterior vaginal wall. These fibers connect the vagina to the lateral walls of the rectum and to the sacrum and separate the midline rectovaginal space from the pararectal space.

Clinical Correlation

The rectovaginal space contains loose areolar tissue and is opened easily with finger dissection during abdominal surgery. During vaginal suspension procedures, perforation of the rectal pillar fibers allows access to the sacrospinous ligaments used in vaginal suspension procedures (see Section 41-19, Hysterectomy).

The posterior cul-de-sac peritoneum extends down the posterior vaginal wall 2 to 3 cm inferior to the posterior vaginal fornix (Kuhn, 1982). Thus, posterior entry into the peritoneal cavity during vaginal surgery is simplified. Posterior entry is done readily by incising the vaginal wall in the area of the posterior fornix (see Section 41-20, Vaginal Hysterectomy).

Vaginal Support

The main support of the vagina is provided by the interaction between the levator ani muscles and the connective tissue that attaches the lateral walls of the vagina to the pelvic walls. Although the visceral connective tissue in the pelvis is continuous and interdependent, DeLancey (1992) has described three levels of vaginal connective tissue support that help to explain various clinical manifestations of pelvic support dysfunction.

Upper Vaginal Support

The parametria continues down the vagina as the paracolpium (see Fig. 38-11). This tissue attaches the upper vagina to the pelvic wall, suspending it over the pelvic floor. These attachments are also known as *level I support* or the *suspensory axis* . They provide connective tissue support to the vaginal apex after hysterectomy. In the standing position, level I support fibers are vertically oriented. Clinical manifestations of level I support defects include posthysterectomy vaginal vault prolapse.

Midvaginal Support

The lateral walls of the midportion of the vagina are attached to the pelvic walls on each side by visceral connective tissue known as *endopelvic fascia.* These lateral attachments of the vaginal walls blend into the arcus tendineus fascia pelvis and the medial aspect of the levator ani muscles. In doing so, these lateral attachments create the anterior and posterior lateral vaginal sulci. These sulci run along the vaginal sidewalls and give the vagina an H shape when viewed in cross section (see Fig. 38-11). The *arcus tendineous fascia pelvis* is a condensation of fascia covering the medial aspect of the obturator internus and levator ani muscles (see Fig. 38-7). It spans from the inner surface of the pubic bones to the ischial spines. Attachment of the anterior vaginal wall to the levator ani muscles is responsible for the bladder neck elevation noted with cough or Valsalva (see Fig. 38-8). Therefore, these attachments may have significance for stress urinary continence. The midvaginal attachments are referred to as *level II support* or the *attachment axis.* Clinical manifestations of level II support defects include anterior and posterior vaginal wall prolapse and stress urinary incontinence.

Distal Vaginal Support

The distal third of the vagina is attached directly to its surrounding structures (see Fig. 38-8). Anteriorly, the vagina is fused with the urethra, laterally it attaches to the pubovaginalis muscle and perineal membrane, and posteriorly it attaches to the perineal body. These vaginal attachments are referred to as *level III support* or the *fusion axis.* They are considered the strongest of the vaginal support components. Failure of this level of support can result in distal rectoceles or perineal descent. Anal incontinence also may result if the perineal body is absent, as may follow obstetric trauma.

Vaginal Blood Supply, Lymphatics, and Innervation

The main blood supply to the vagina arises from the descending or cervical branch of the uterine artery and from the vaginal artery, a branch of the internal iliac (see Fig. 38-15). These vessels form an anastomic arcade along the lateral sides of the vagina at the level of the vaginal sulci. They anastomose with the contralateral vessels on the anterior and posterior walls of the vagina. Additionally, the middle rectal artery from the internal iliac contributes to supply the posterior vaginal wall. The distal walls of the vagina also receive contributions from the internal pudendal artery.

Lymphatic drainage of the upper two thirds of the vagina is similar to that of the uterus, as described earlier. The distal part of the vagina drains with the vulvar lymphatics to the inguinal nodes. A more detailed description of the vulvar lymphatics is presented in the vulva and perineum section of this chapter.

The vagina receives its nerve supply from the inferior extensions of the uterovaginal plexus, a component of the inferior hypogastric or pelvic plexus (Inferior Hypogastric Plexus).

LOWER URINARY TRACT STRUCTURES

Bladder

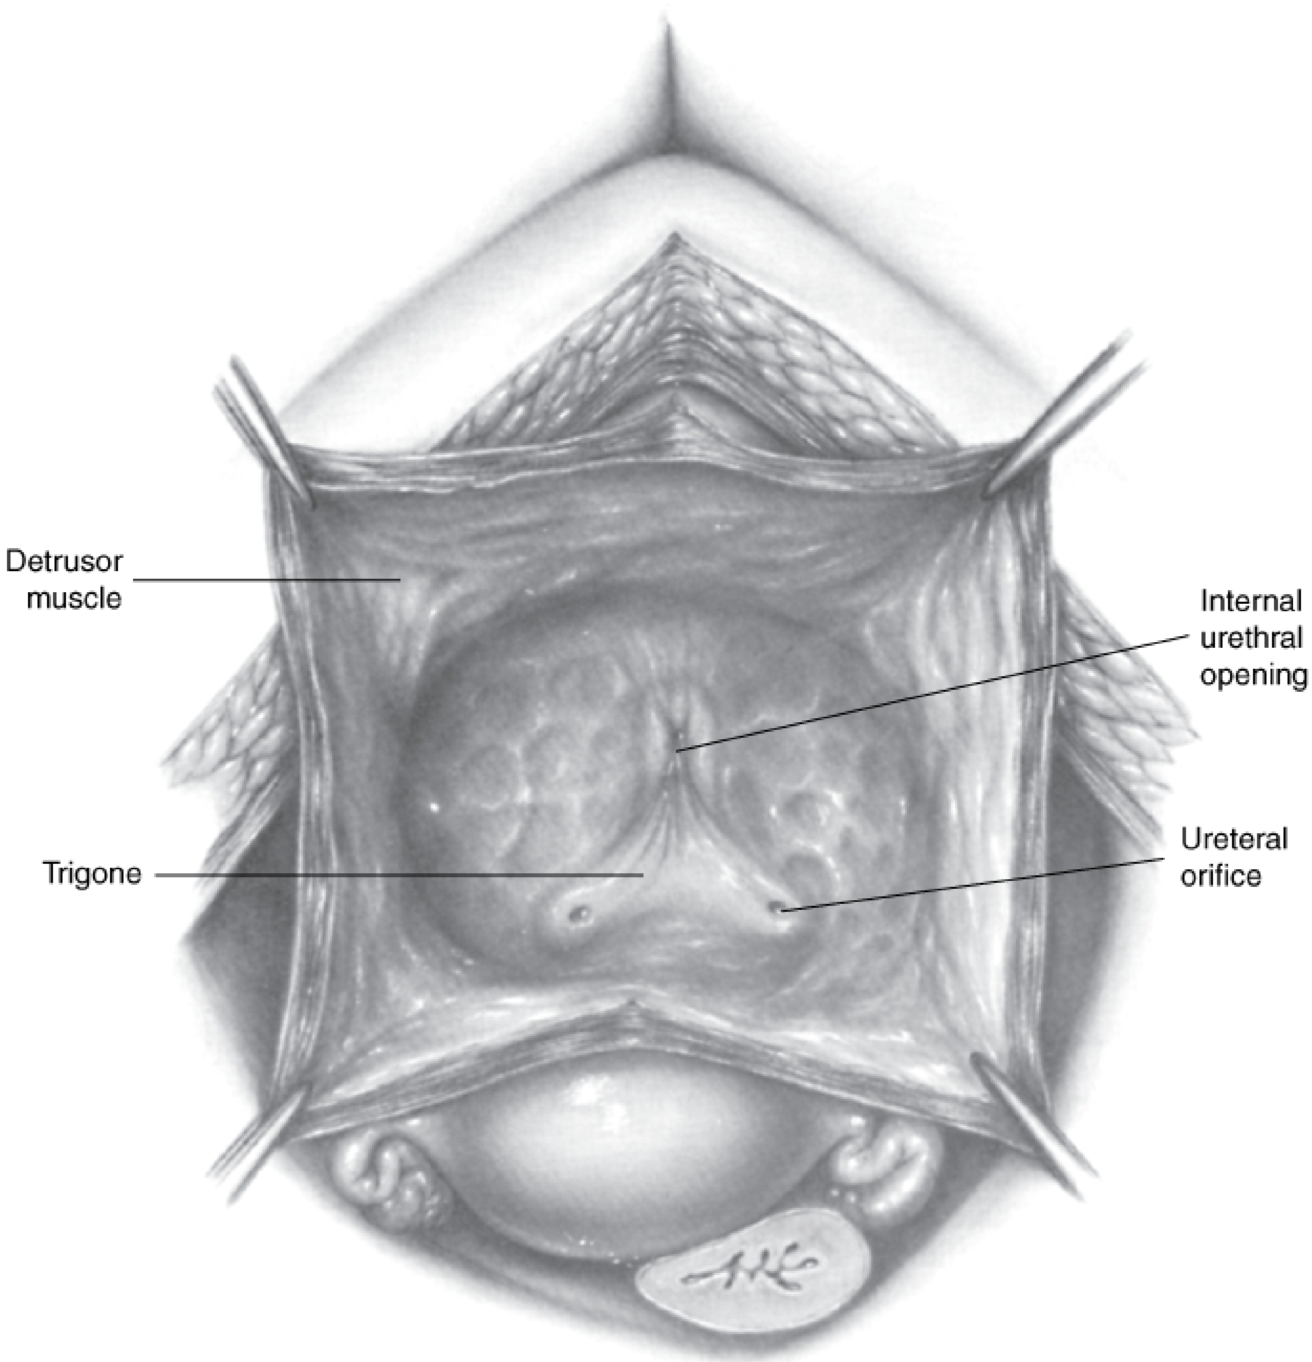
The bladder is a hollow organ that allows storage and evacuation of urine (see Fig. 38-14). Anteriorly, the bladder rests against the anterior abdominal wall, and posteriorly, it rests against the vagina and cervix. Inferiorly and laterally, the bladder is in contact with the inner surface of the pubic bones. In these areas, the bladder is devoid of peritoneal covering. The reflection of the bladder onto the abdominal wall is triangular in shape. The apex of this triangle is continuous with the median umbilical ligament (see Fig. 38-12).

Clinical Correlation

Because the apex of the bladder is highest in the midline, this is the area where bladder injury is most likely to result during peritoneal entry.

The bladder wall consists of coarse bundles of smooth muscle known as the *detrusor muscle* , which extends into the upper part of the urethra (Fig. 38-19). Although separate layers of the detrusor are described, they are not as well defined as the layers of other viscous structures, such as the bowel or the ureter (see Fig. 23-2). The innermost layer of the bladder wall is plexiform and can be seen from the pattern of trabeculations noted during cystoscopy. The mucosa of the bladder consists of transitional epithelium.

FIGURE 38-19



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Dome of the bladder is opened to display trigone anatomy and bladder wall muscle. *(From Thompson, 1997, with permission.)*

The bladder can be divided into a dome and a base approximately at the level of the ureteral orifices. The dome is thin-walled and distensible, whereas the base has a thicker wall that undergoes less distention during filling. The bladder base consists of the vesical trigone and the detrusor loops. These loops are two U-shaped bands of fibers found at the vesical neck, the area where the urethra enters the bladder wall (see Fig. 38-19).

The blood supply to the bladder arises from the superior and inferior vesical arteries. The superior vesical arteries are branches of

the patent portion of the umbilical artery. The inferior vesical artery, when present, arises from either the internal pudendal or the vaginal artery.

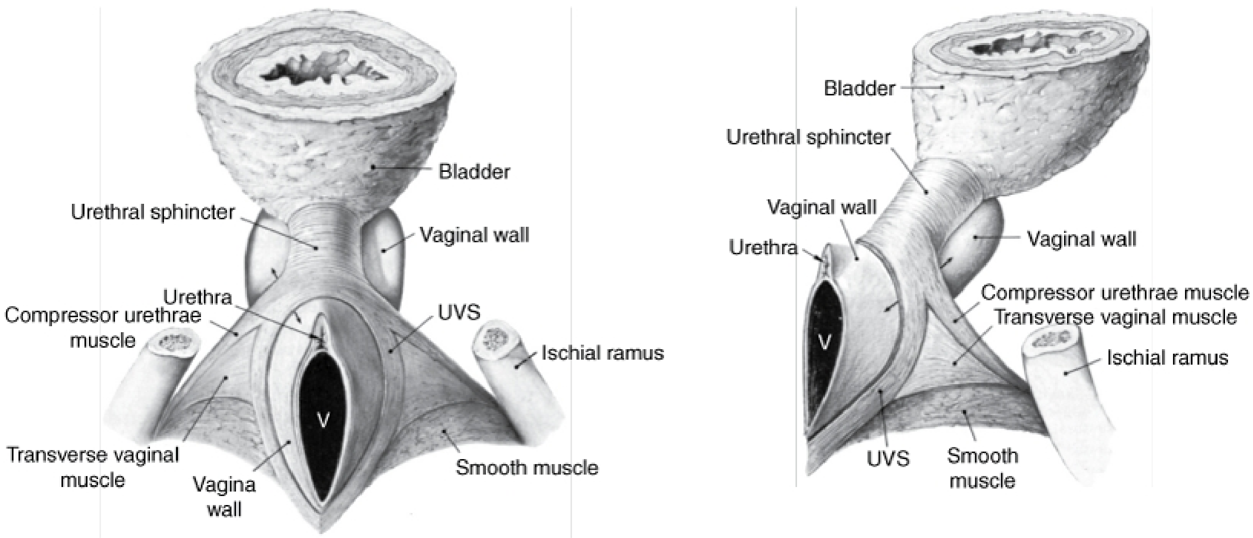
The nerve supply to the bladder arises from the vesical plexus, a component of the inferior hypogastric plexus (Inferior Hypogastric Plexus).

Urethra

The female urethra is a complex organ that is 3 to 4 cm in length. The lumen of the urethra begins at the internal urinary meatus and then courses through the bladder base for less than a centimeter. This region of the bladder where the urethral lumen traverses the bladder base is called the *vesical neck.* The distal two thirds of the urethra are fused with the anterior vaginal wall.

The walls of the urethra begin outside the bladder wall. They consist of two layers of smooth muscle, an inner longitudinal and an outer circular layer. This outer layer, in turn, surrounded by a circular layer of skeletal muscle referred to as the *sphincter urethra* or *rhabdosphincter* (see Fig. 23-5). Approximately at the junction of the middle and lower thirds of the urethra and just above the perineal membrane, two strap skeletal muscles known as the *urethrovaginal sphincter* and *compressor urethrae* are found. These muscles were known previously as the *deep transverse perineal muscles* in females. Combined, the urethrovaginal sphincter, the compressor urethrae, and the sphincter urethra constitute the *striated urogenital sphincter complex* (Fig. 38-20). Together, these three muscles function as a unit and have a complex and controversial innervation, as described below. Their fibers combine to provide constant tonus, with emergency reflex activity mainly in the distal half of the urethra.

FIGURE 38-20



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Striated urogenital sphincter complex in the female. The perineal membrane has been removed. UVS = urethrovaginal sphincter; V = vagina; VW = vaginal wall. *(From Oelrich, 1983, with permission.)*

Distal to the level of the perineal membrane, the walls of the urethra consist of fibrous tissue, serving as the nozzle that directs the urine stream. The urethra has a prominent submucosal layer that is lined by hormone-sensitive stratified squamous epithelium. Within the submucosal layer on the dorsal or vaginal surface of the urethra is a group of glands known as the *paraurethral glands* that open into the lumen of the dorsal surface of the urethra (see Fig. 26-4). Duct openings of the two most prominent glands, termed *Skene glands,* are seen on the inner surface of the external urethral orifice.

Clinical Correlation

Obstruction of the paraurethral gland ducts can result in cyst formation, and chronic infection of the paraurethral glands can lead to urethral diverticula (see Chap. 26, Classification).

The urethra receives its blood supply from branches of the vesical and internal pudendal arteries. The pudendal nerve innervates the most distal part of the striated urogenital sphincter complex. Somatic efferent branches of the pelvic nerve, a component of the inferior hypogastric or pelvic plexus, variably innervate the sphincter urethra.

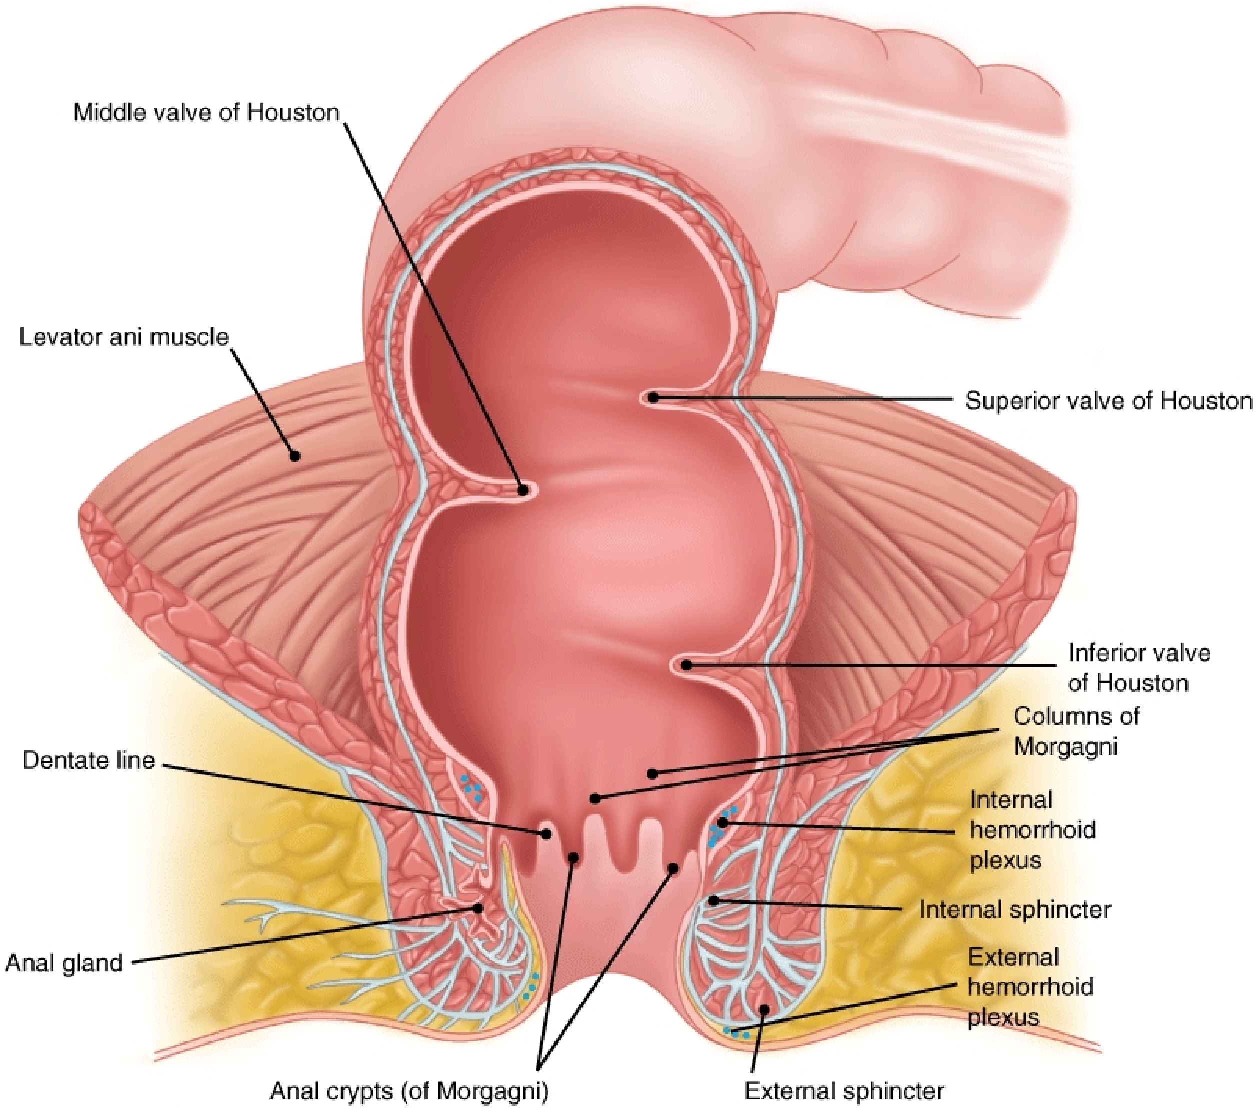
Ureters

A detailed description of the pelvic ureter appears in the discussion of pelvic sidewall anatomy (Pelvic Sidewall).

RECTUM

The rectum is continuous with the sigmoid colon approximately at the level of the third sacral vertebra. It descends on the anterior surface of the sacrum for about 12 cm and ends in the anal canal after passing through the levator hiatus (see Fig. 38-7). The anterior and lateral portions of the proximal two thirds of the rectum are covered by peritoneum. The peritoneum is then reflected onto the posterior vaginal wall, forming the posterior cul-de-sac of Douglas, also termed the *rectouterine pouch* (see Fig 38-14). In females, the cul-de-sac is located approximately 5 to 6 cm from the anal orifice and can be palpated manually during rectal or vaginal examination (see Fig. 1-7). At its commencement, the rectal wall is similar to that of the sigmoid, but near its termination, it becomes dilated to form the rectal ampulla, which begins below the posterior cul-de-sac peritoneum (Fig. 38-21).

FIGURE 38-21



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Rectal anatomy. *(From Pfenninger, 2001, with permission.)*

The rectum contains several (usually three) transverse folds, *plicae transversales recti,* also termed *valves of Houston* . The largest and most constant of these folds is located anteriorly and to the right, approximately 8 cm from the anal orifice. These folds may contribute to fecal continence by supporting fecal matter above the anal canal.

Clinical Correlation

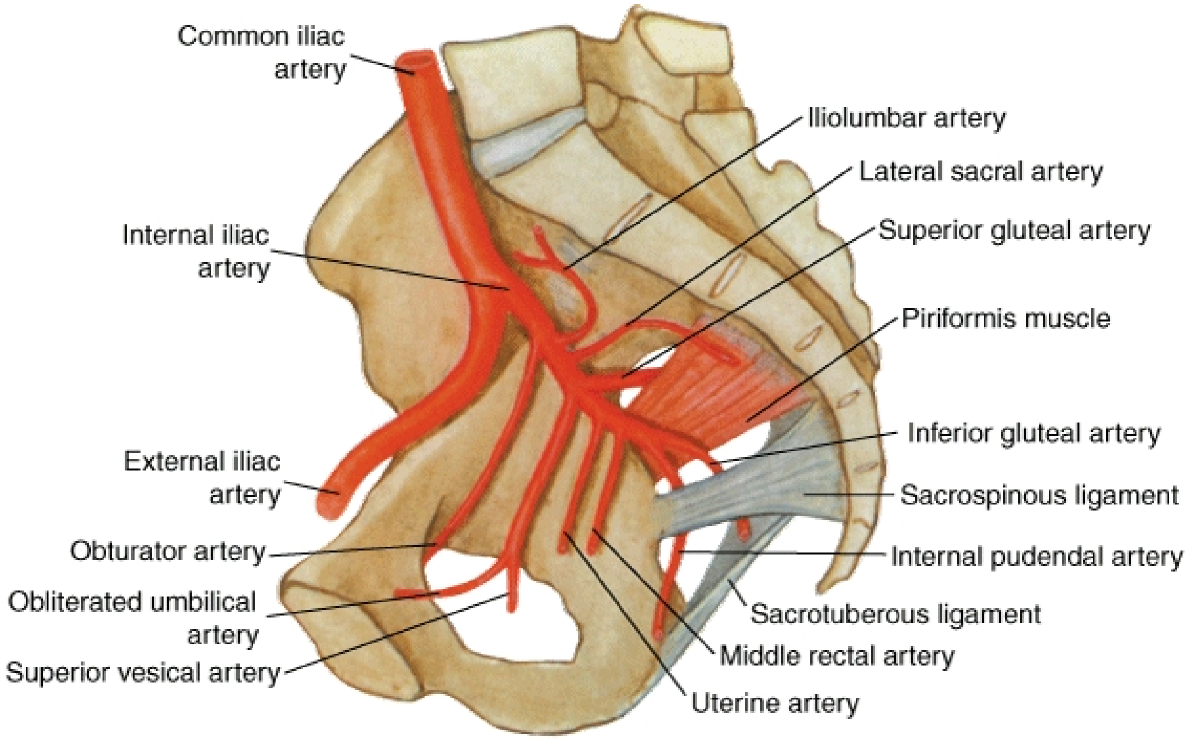
In the empty state, the transverse rectal folds overlap each other, making it difficult at times to manipulate an examining finger or endoscopic tube past this level.

Pelvic Blood Supply

The pelvic organs are supplied by the visceral branches of the internal iliac (hypogastric) artery and by direct branches from the abdominal aorta (Fig. 38-22). The internal iliac artery generally divides into anterior and posterior divisions in the area of the greater sciatic foramen. Each division has three parietal branches that supply nonvisceral structures. The *iliolumbar* , *lateral sacral* , and *superior gluteal arteries* are the three parietal branches of the posterior division. The *inferior gluteal, internal pudendal,* and

obturator arteries are parietal branches that most commonly arise from the anterior division. The remaining branches of the anterior division supply the pelvic viscera (bladder, uterus, vagina, and rectum). These include the *uterine* , *vaginal* , and *middle rectal arteries* and the *superior vesical arteries* , which commonly arise from the patent part of the umbilical arteries.

FIGURE 38-22



Source: Schorge JO, Schaffer JI, Halvorson LM, Hoffman BL, Bradshaw KD, Cunningham FG: *Williams Gynecology*: http://www.accessmedicine.com

Pelvic arteries. *(From Clemente, 1997, with permission.)*

The two most important branches of the aorta that contribute to the blood supply of the pelvic organs are the *superior rectal* and *ovarian arteries* (see Fig. 38-15). The superior rectal arteryis the terminal branch of the inferior mesenteric artery. The superior rectal arteries anastomoses with the middle rectal arteries, thus contributing blood supply to the rectum and vagina. The ovarian arteries arise directly from the aorta just inferior to the renal vessels. The ovarian arteries anastomose with the ascending branch of the uterine artery. These anastomoses contribute to the blood supply of the uterus and adnexa.

Other important anastomoses between the aorta and internal iliac arteries include those of the middle sacral and lumbar arteries with the lateral sacral and iliolumbar arteries, respectively.

Pelvic Innervation

Nerve supply to the visceral structures in the pelvis (bladder, urethra, vagina, uterus, adnexa, and rectum) arises from the autonomic nervous system. The two most important components of this system in the pelvis include the *superior* and *inferior hypogastric plexuses* .

SUPERIOR HYPOGASTRIC PLEXUS

The superior hypogastric plexus, also known as the *presacral nerve,* is an extension of the aortic plexus found below the aortic bifurcation (Fig. 38-23A). This plexus contains primarily sympathetic fibers and sensory afferent fibers from the uterus.

A. Pelvic innervation **B.** Superior and inferior hypogastric plexuses. *(From Anson, 1950, with permission.)*

The sensory afferent fibers contained within the superior hypogastric plexus are targeted in presacral neurectomy, a surgical procedure performed to treat dysmenorrhea and central pelvic pain refractory to medical management (see Chap. 11, Neurolysis).

INFERIOR HYPOGASTRIC PLEXUS

The superior hypogastric plexus terminates by dividing into the *hypogastric nerves* . These nerves join parasympathetic efferents from the second through the fourth sacral nerve roots (pelvic splachnic nerves, also termed *nervi erigentis*) to form the inferior hypogastric plexus, also known as the *pelvic plexus* (Fig. 38-23B).

Fibers of the inferior hypogastric plexus accompany the branches of the internal iliac artery to the pelvic viscera. Accordingly, they are divided into three portions: the vesical, uterovaginal (Frankenhauser ganglion), and middle rectal plexuses. Extensions of the

inferior hypogastric plexus reach the perineum along the vagina and urethra to innervate the clitoris and vestibular bulbs.

Injury to the branches of the inferior hypogastric plexus during cancer debulking or other extensive pelvic surgeries can lead to varying degrees of voiding, sexual, and defecatory dysfunction.

Retroperitoneal Surgical Spaces

Knowledge of a number of retroperitoneal spaces is important for the pelvic surgeon. These spaces include the pelvic sidewall, the presacral space, and prevesical space.

PELVIC SIDEWALL

The retroperitoneal space of the pelvic walls contains the internal iliac vessels and pelvic lymphatics, pelvic ureter, and obturator nerve. Entering this space is especially useful for identifying the ureter and for ligating the uterine or internal iliac arteries in the setting of hemorrhage.

Vessels

The major pelvic vessels are shown in Figure 38-22. The internal iliac artery and vein are within the pelvic sidewall retroperitoneal space. If these vessels are dissected, such as for internal iliac or uterine artery ligation, the ureter must be avoided. Ligation of the internal iliac artery is usually done to decrease the pulse pressure to pelvic organs. The vessel should be ligated distal to the origin of the posterior division branches in an effort to prevent significant devascularization of the gluteal muscles. These branches generally arise from the lateral wall of the internal iliac artery about 3 to 4 cm from its division off the common iliac artery.

Pelvic Ureter

The ureter enters the pelvis by crossing over the bifurcation of the common iliac artery just medial to the ovarian vessels (see Figs. 38-12 and 38-15). It descends into the pelvis attached to the medial leaf of the pelvic sidewall peritoneum. Along this course, the ureter lies medial to the internal iliac branches and anterolateral to the uterosacral ligaments. The ureter then traverses the cardinal ligament approximately 1 to 2 cm lateral to the cervix. Near the level of the uterine isthmus, it courses below the uterine artery ("water under the bridge") (see Fig. 38-13 and Fig. 38-14). It then travels anteromedially toward the base of the bladder (see Fig. 38-15). In this path, it runs close to the upper third of the anterior vaginal wall. Finally, the ureter enters the bladder and travels obliquely for approximately 1.5 cm before opening at the ureteral orifice (see Fig. 38-19).

The pelvic ureter receives blood supply from the vessels it passes: the common iliac, internal iliac, uterine, and vesical vessels. Vascular anastomoses on the connective tissue sheath enveloping the ureter form a longitudinal network of vessels.

Because of the pelvic ureter's proximity to many structures encountered during gynecologic surgery, emphasis should be placed on its precise intraoperative identification.

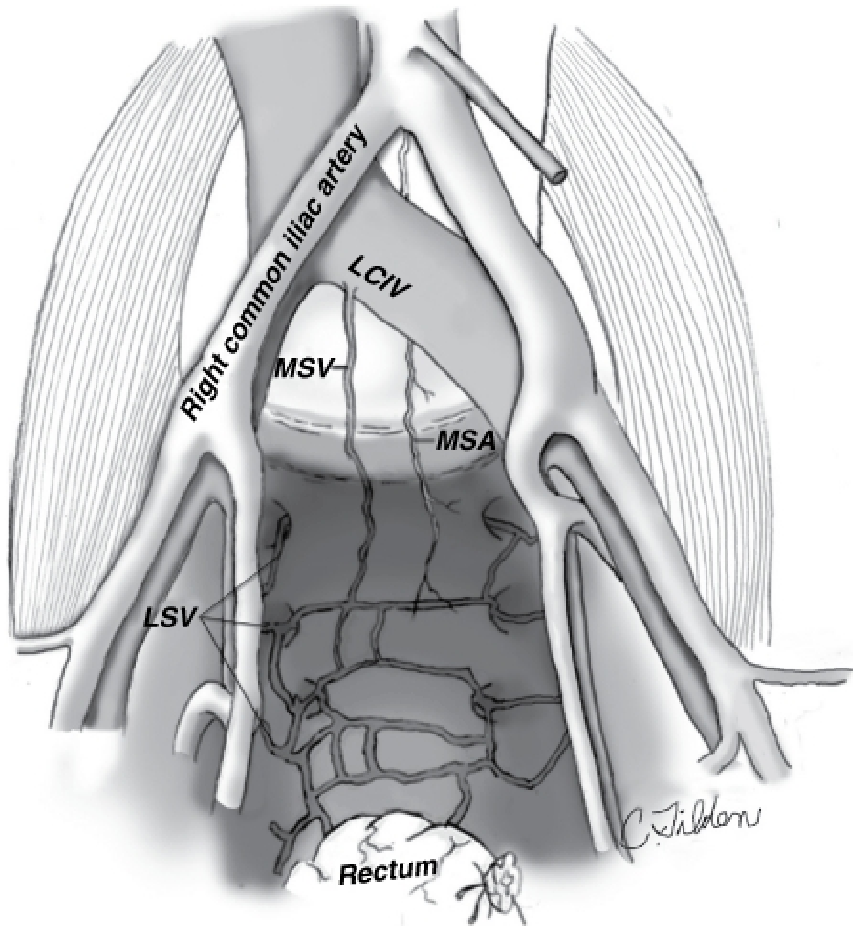
Clinical Correlation

Most ureters are injured during gynecologic surgery for benign disease. Over 50 percent of these injuries are not diagnosed intraoperatively. The most common sites of injury include: (1) the pelvic brim during clamping of the infundibulopelvic ligament, (2) the uterine isthmic region during uterine artery ligation, (3) the pelvic sidewall during suturing of the uterosacral ligament, and (4) the vaginal apex during clamping or suturing of the vaginal cuff.

PRESACRAL SPACE

This retroperitoneal space is located between the sacrum and the rectosigmoid and posterior abdominal wall peritoneum. It begins below the aortic bifurcation and extends inferiorly to the pelvic floor. Laterally, this space is bounded by the internal iliac vessels and branches (Fig. 38-24). Contained within the loose areolar and connective tissue of this space are the superior hypogastric plexus, hypogastric nerves, and portions of the inferior hypogastric plexus (Fig. 38-23).

FIGURE 38-24



Presacral space. LCIV = left common iliac vein; LSV = lateral sacral veins; MSA = middle sacral artery; MSV = middle sacral vein.

The vascular anatomy of the presacral space is complex and includes an extensive and intricate venous plexus, termed the *sacral venous plexus.* This plexus is formed primarily by the anastomoses of the middle and lateral sacral veins on the anterior surface of the sacrum (Fig. 38-24). The middle sacral vein commonly drains into the left common iliac vein, whereas the lateral sacral vein opens into the internal iliac vein. Ultimately, these vessels drain into the caval system. The sacral venous plexus also receives contributions from the lumbar veins of the posterior abdominal wall and from the basivertebral veins that pass through the pelvic sacral foramina.

The middle sacral artery, which courses in proximity to the middle sacral vein, arises from the posterior and distal parts of the abdominal aorta. In a recent study that looked at the vascular anatomy of the presacral space, the left common iliac vein was the closest major vessel identified both cephalad and lateral to the midsacral promontory. The average distance of the left common iliac vein to the midsacral promontory in this study was 2.7 cm (range 0.9 to 5.2 cm) (Wieslander, 2006).

Clinical Correlation

The presacral space is entered by gynecologists to perform abdominal sacrocolpopexy (see Sections 42-17, Abdominal Sacrocolpopexy) and presacral neurectomies. The proximity of the left common iliac vein to the sacral promontory makes this vessel especially vulnerable to injury during entrance into and dissection within this space. Additionally, bleeding from the sacral venous plexus may be difficult to control because the veins often retract into the sacral foramina.

PREVESICAL SPACE

This space is also called the *retropubic space* or *space of Retzius.* It can be entered by incising the transversalis fascial layer of the anterior abdominal wall. As shown in Figure 38-25, this space is bounded anteriorly and laterally by the bony pelvis and muscles of the pelvic wall. This space is closed by the anterior abdominal wall superiorly. The bladder and proximal urethra lie posterior to this space. Attachments of the paravaginal connective tissue to the arcus tendineus fascia pelvis constitute the posterolateral limit of the space and separate it from the vesicovaginal and vesicocervical spaces.

Retropubic space.

There are a number of vessels and nerves in this space. The *dorsal vein of the clitoris* passes under the lower border of the pubic symphysis and drains into the periurethral-perivesical venous plexus, also termed the *plexus of Santorini.* The obturator neurovascular bundle courses along the lateral pelvic walls and enters the obturator canal to reach the medial compartment of the thigh. The autonomic nerve branches that supply the bladder and urethra course on the lateral borders of these structures. Additionally, in most women, accessory obturator vessels that arise from the inferior epigastric or external iliac vessels are found crossing the superior pubic rami and connecting with the obturator vessels near the obturator canal.

Clinical Correlation

Injury to the obturator neurovascular bundle or accessory obturator vessels is most often associated with pelvic lymph node dissections and paravaginal defect repair procedures. Thus, knowledge of the approximate location of these vessels and of the obturator canal is critical when this space is dissected. The obturator canal is found approximately 5 to 6 cm from the midline of the pubic symphysis and 1 to 2 cm below the upper margin of the iliopectineal ligament (Drewes, 2005).

Bleeding from the periurethral-perivesical venous plexus is often encountered while placing the sutures or passing the needles into

this space during retropubic bladder neck suspensions and midurethral retropubic procedures, respectively. This venous ooze usually stops when pressure is applied or the sutures are tied.

VULVA AND PERINEUM

Vulva

The external female genitalia, collectively known as the *vulva,* lie on the pubic bones and extends posteriorly under the pubic arch. Structures included are the mons pubis, labia majora, labia minora, clitoris, vestibule, vestibular bulbs, greater vestibular (Bartholin) glands, lesser vestibular glands, paraurethral (Skene) glands, and the urethral and vaginal orifices (Fig. 38-26). The embryologic development of these structures can be found in Chapter 18.

External female genitalia. *(From Cunningham, 2005, with permission.)*

MONS PUBIS AND LABIA MAJORA

The *mons pubis* , also called the *mons veneris* , is the rounded eminence that lies anterior to the pubic symphysis. The *labia majora* are two prominent folds that extend from the mons pubis anteriorly toward the perineal body posteriorly. Skin over the mons pubis and labia majora contains hair and has a subcutaneous layer similar to that of the anterior abdominal wall. The subcutaneous layer consists of a superficial fatty layer similar to Camper fascia and a deeper membranous layer, called *Colles fascia.* Also known as the *superficial perineal fascia,* Colles fascia is similar and continuous with Scarpa fascia of the anterior abdominal wall (see Fig. 38-4).

Clinical Correlation

Colles fascia attaches firmly to the ischiopubic rami laterally and the perineal membrane posteriorly. These attachments prevent the spread of fluid, blood, or infection from the superficial perineal space to the thighs or posterior perineal triangle. Anteriorly, Colles fascia has no attachments to the pubic rami, and it is therefore continuous with the lower anterior abdominal wall. This continuity may allow the spread of fluid, blood, and infection between these compartments.

The round ligament and obliterated processus vaginalis, also termed the *canal of Nuck,* exit the inguinal canal and attach to the adipose tissue or skin of the labia majora (see Fig. 38-4). Thus, the differential diagnosis of a mass in the labium majus should include a leiomyoma arising from the round ligament or a persistent processus vaginalis. A congenital inguinal hernia also may reach the labium majus.

LABIA MINORA

These two cutaneous folds lie between the labia majora (Fig. 38-26). Anteriorly, each labium minus bifurcates to form two folds that surround the glans of the clitoris. The *prepuce* is the anterior fold that overlies the glans, and the *frenulum* is the fold that passes below the clitoris. Posteriorly, the labia minora end at the fourchette.

In contrast to the skin that overlies the labia majora, the skin of the labia minora does not contain hair. Also, the subcutaneous tissue is devoid of fat and consists primarily of loose connective tissue. This latter attribute allows mobility of the skin during intercourse and accounts for the ease of dissection with vulvectomy.

Clinical Correlation

Typically, labia minora are symmetric, but their size and shape can vary widely between women. In some, these winglike structures are pendulous and can be drawn into the vagina during coitus. If associated with dyspareunia in this setting, the labia can be reduced surgically (see Section 41-10, Labial Minora Reduction). Moreover, chronic dermatologic diseases such as lichen sclerosus may lead to significant atrophy or disappearance of the labia minora (see Chap. 4, Lichen Sclerosus).

CLITORIS
